1 Secondary Markets

If we have two parties that want to exchange goods, they can meet up, decide on a price, and exchange the good. However, when it comes to many players, we must make some sort of exchange. We go over the construction of one.

Definition 1.1 (Securities)

A **security** refers to a fungible (able to be traded), negotiable financial instrument that holds some type of monetary value. It can represent:

1. an ownership position in a publicly-traded corporation via stock (*equity*)
2. a creditor relationship with a governmental body or a corporation represented by owning that entity bond (*debts*)
3. or rights to ownership as represented by an option.

Generally, they can be divided into **equity** and **debts**.

Definition 1.2 (IOU)

An **IOU** is a phonetic acronym of the words "I owe you," and is a written document that acknowledges the existence of a debt. It is conventionally used for less formal documents.

Definition 1.3 (Counterparty Risk)

Counterparty risk is the likelihood or probability that one of those involved in a transaction might default on its contractual obligation. It can exist in credit, investment, and trading transactions.

Definition 1.4 (Credit Quality)

Credit quality is a measurement of an individual's or company's creditworthiness, or the ability to repay its debt. It can also be seen as a measure of the level of counterparty risk to the lender/creditor. They are measured by private independent **credit rating agencies**, the most popular being

1. Standard & Poor's
2. Moody's
3. Fitch

each with its own designations, ranging from

1. high **investment-grade**: AAA to AA
2. medium **investment-grade**: A to BBB
3. low **junk, high-yield, or subprime**: BB, B, CCC, CC, C
4. Already in default: D

Credit scores can be assigned to multiple things:

1. **Bond ratings** are used to determine the risk that the bond issuer will default on its payments.
2. **Corporate credit ratings** are based on a firm's financial statements, including the specific company's capital structure, credit payment history, revenue, and earnings.
3. **FICO scores** determine an individual's credit quality for credit card expenses, mortgages, auto loans, etc. It ranges from 300-850.

Investing in securities issued by the U.S. treasury is considered the absolute safest way to invest in bonds, then bluechip corporations, and then smaller companies.

Note that if a security has a lower credit quality, the risk of default is greater and these securities may have greater potential profits (e.g. pay more interest, better dividends, great potential, etc.)

1.1 Counterparties and Clearing Houses

Trader, Broker, Liquidity provider, Market maker

NYSE is a stock exchange that leases a space to different market makers (banks, hedge funds). It also makes money through fees from companies to be listed on NYSE. If a crash happens (i.e. a market maker buys a stock and it tanks before they can sell it), then the market makers get screwed.

Think about when one party buys stocks or bonds. Their downside is limited to the amount they paid on the stock, but there are many other cases where they may not be protected.

Definition 1.5 (Default)

If a borrower fails to pay back a debt or cover a loss, then they **default**.

Example 1.1 (Risks Associated with Trades)

1. The simplest case is when they are in debt. They want to borrow X for a certain time, and repay it back in a year at some interest rate $X(1+r)$. However, they may not have the money by then.
2. When they short a stock, they can borrow money from another party that owns the stock, sell it, and buy it back at a lower price. However, if the price of the stock rises, then they must pay even more money to buy it back, and they may not have enough money to.
3. When they buy a stock on margin, they borrow money from a broker to buy the stock, and they must pay back the broker with interest. However, the price of the stock may fall and the borrower, even after liquidating the stock, may not have enough money to pay back the broker.
4. Someone who longs a forward contract may not have enough money to pay the difference between the forward price and the spot price.

Definition 1.6 (Counterparty)

A **counterparty** is the other party in a financial transaction.

Note that in a vanilla exchange, the two parties trading are counterparties to each other. This is called a **bilateral exchange**. As we have seen, this is risky since if one party defaults, the other party is left with nothing. Therefore, the markets introduce a middleman that takes care of this risk.

Definition 1.7 (Clearing House)

The **clearing house** is an entity that is counterparty to all parties. This means that if party A and party B want to trade, they must go through the clearing house. The clearing house buys from B and sells to A. Therefore, the counterparty risk is now within the clearing house.

It seems that we have simply moved the risk from the traders to the clearinghouse, and this is correct. The traders are glad that the risk is gone from them since they will always be paid by the clearinghouse, and the clearinghouse can add additional regulations on trading to reduce the risk of default. The first regulation they should impose are margin requirements.

Definition 1.8 (Margin)

Margin is simply cash or some other asset (stocks, bonds, etc.) that can be used as collateral during a trade. Note that this does not mean that the collateral must be invested into anything. It is just restricted to sit there in your bank account.

1. Cash is the most liquid form of margin, and is the most common form of margin.

2. Bonds are also a common form of margin, and Treasury bonds are usually valued at 90% of their market value.
3. Stocks are also a common form of margin, and are usually valued at 50% of their market value.

The margin requirements are generally very inflexible unless you have a good relationship with your broker and are a big trader. Now that we've seen the important roles that a clearing house plays, we look at the development of more complex markets, namely, the exchange and OTC markets.

1.2 Exchange vs OTC Markets

In a trading floor or pit, there are groups of traders huddled at certain physical locations that trade a certain asset, like corn futures. Back then, there would be individual traders that have their own small capital that they can trade with, called **locals**, but they have been dominated by traders that work for large financial institutions, causing locals to be either pushed out or joined with the firms. Market making firms like Akuna have pit traders, who have headsets and tablets, that are in real-time communication with the screen traders upstairs.

Standing in the perimeter of the trader circle are the **brokers**, who relay orders between the traders in the pit and outside of the pit. These brokers also have devices that allow them to communicate with **off floor** parties, who are individuals that are interested in these products.

Example 1.2 (Off Floor Parties)

Some examples of off floor parties are:

1. Hedge funds, who have devised trading strategies that they want to implement, e.g. using drones to look at the harvest quantity. Now they want to gain exposure to the corn market.
2. Banks might also want to use client money to develop a trading strategy.
3. Consumers such as Kellogs (which needs a lot of corn to make cereal) might be interested in buying contracts to hedge their underlying exposure.
4. Producers like corn farmers might want to buy some contract to lock in the price in which they can sell it at.
5. Large funds like pension funds or family money.
6. Retail investors like small, non-professional traders that might dabble in options.
7. Other market makers might be connected to these brokers

There is specific terminology that we should introduce first.

Definition 1.9 (Bid, Offer)

Now if some off floor party decides to sell some calls, they will call their broker and ask to quote some prices. This means that they are asking for bid and offer prices. These traders might quote the following prices:

When more people want to buy and sell things, they must go to an **exchange**, which is literally a physical space that is leased to various parties (e.g. large banks, hedge funds) so that they can exchange goods. These exchanges also collect money through fees from companies to be listed on NYSE. There are two big exchanges, the NYSE and the NASDAQ, in the U.S., both located in New York.

Us retail traders are not direct participants of the exchange; the parties that participate there are called the **market makers**, or **liquidity providers**. Market makers, usually large banks or financial institutions (like hedge funds), make sure that there is enough trading volume to ensure liquidity in the market. A buyer and a seller must meet together to complete a deal, and to ensure that this happens smoothly (i.e. provides liquidity), a market maker buys stocks (through the individual's brokerage) and sells them to the corresponding recipient. Essentially, they provide a pool of shares and act as intermediaries between them. They profit from the bid-ask spread, though sudden volatility is always a risk. For example, if a crash

happens (i.e. a market maker buys a stock and it tanks before they can sell it), then the market makers get screwed because they are left with an undervalued stock.

The trader cannot directly trade through the market makers. They must contact their **broker**, which is another company that acts as an intermediary. If I want to buy a stock, my buy order gets sent to my broker, which gets sent to the market makers, which pairs me up with a seller through their own broker, and the transaction is completed. These brokers make money through commissions from the traders and from trading in dark pools, which we'll talk about later. They also give access to traders the forecasts of analyst reports for companies and other research.

Clearly, there can be some shady stuff going on here, but luckily, the SEC and the FINRA consistently regulate the markets to ensure fairness for the little players (retail investors). One of the most important regulations is the 2005 Regulation NMS (National Market System), which required exchanges to publish the best bid and offer price for each stock, required them to route orders to the trading venue with the best price, and had set the minimal price quotation increment to \$0.01. This ensured transparency and protection of the investor with the best price execution (but this can be taken advantage of by high frequency traders).

Definition 1.10 (Exchange Markets)

Exchange markets are markets that exchange *standardized* contracts and is *highly regulated* (to protect investors) by a central authority. A buyer and seller come together to trade a contract, and they enter the contract through a **clearing house**, which is the *counterparty* to all trades. That is, both the buyer and seller enter into a contract with the clearing house. Doing this reduces the counterparty risk by ensuring that both sides have adequate *margin*. For example, if the buyer wins the bet and the seller can't pay, the clearing house will pay the buyer.

Question 1.1 ()

Talk about counterparties, clearinghouses.

1.2.1 Market Making and High Frequency Trading

A significant mover of markets are **high frequency traders**, or HFTs. HFT is a type of algorithmic trading that are characterized by high speeds and high turnover rates. It is the primary type of algorithmic trading and consists of about 50% of all equity trades in the U.S. There is an average of about 1 trader per 10 milliseconds. Whether HFT is beneficial is very controversial:

1. Some argue that it is good since it increases liquidity and lowers transaction costs for retail investors. Even for potentially risky stocks (e.g. very overvalued), HFTs will always make a market out of them.
2. It can be considered unfair because it gives a huge advantage to HFT firms through front-running and other short-term strategies. This also increases the probability of **flash-crashes** (e.g. 2010 flash crash).

Unsurprisingly, many HFT firms are market makers due to their ability to provide liquidity.

The primary form of HFT is **scalping**, which profits off of small price changes. The multiple benefits and drawbacks are easy to spot:

1. It requires a strict exit strategy since one large loss could eliminate the many small gains the trader worked to obtain.
2. It also requires a much higher ratio of winning trades vs losing ones, while keeping profits roughly equal or slightly bigger than losses.
3. A brief exposure to the market diminishes the probability of running into an adverse event like a crash.
4. Smaller moves are easier to obtain, so there are plenty of opportunities to exploit.

This strategy is extremely sensitive that even the physical location of the firm relative to the exchange matters. Heavy money in infrastructure is invested.

Definition 1.11 (OTC Markets)

In **over the counter markets** (OTC), there is also an interaction between the buyer and the seller, but it is done in two ways.

1. In *bilateral clearing*, the buyer and seller are the counterparties to each other, and so there is indeed the risk of default on one side.
2. Post-2008, there has been a push to clear through a *central counterparty*. Therefore, there has been a slow push to clear OTC derivative trading to reduce this counterparty risk.

Finally, the OTC market is much larger (about 5 to 10 times larger in terms of the principal dollars underlying the assets) than the exchange and is less regulated since most of the players are institutional investors (they don't need as much protection but need more flexibility).

1.3 Stock Prices and Limit Order Books

Now how is the share price determined? There are two large paradigms for this. The first is the **fundamental approach**, which attempts to calculate the intrinsic value for the company by calculating its discounted future cash flows.

$$\text{Present Value} = \sum_{n=1}^{\infty} \frac{\text{Cash Flow}_1}{(1 + R)^n}$$

However, we will concern ourselves with the second approach: the **market approach**, which claims that the stock price is determined by supply and demand. This can be seen by looking at the **limit order book** (LoB), which shows all pending limit orders at the current time. This allows us to see where the prices are concentrated at and how strong the demand is versus the supply. In the diagram below, the right side represent the sell limit orders while the left side represents the buy limit orders. If we submit 50 buy market orders, then the best price is executed.

The market makers profit off of the **bid-ask spread**, which is the difference in the buy and sell price. If a seller wants to sell at \$99.99 and a buyer wants to buy at \$100.00, then the market maker can buy the stock from the seller for \$99.99 and sell it to the buyer at \$100.00, making a \$0.01 profit.

We can also look at it from an economic perspective.

Now, we get to the interesting part. We can construct a market of n entities E_1, \dots, E_n , with each entity having ownership of c_1, \dots, c_n stocks, where $c_i \geq 0$. Remember at the most fundamental level, owning a stock is like owning the profits and voting power of a part of a company, which we can represent as a giant box that churns out cash. By owning one share, we own a part of that box. In this context, we will observe the dynamics of public markets.

We can draw the supply and demand curves for a certain company's stock. We can treat stocks as goods, with the company being the supplier and public investors as the consumers.

1. The demand curve says: as the price for a stock, i.e. a piece of the company, increases the quantity demanded by the market (consumers) will decrease because the costs of buying the stock will outweigh the marginal value of the share. There is a very important distinction to make here between stocks and other type of goods. Unlike consumable goods which we can clearly observe a diminishing marginal value (drinking 1 can of soda vs 2 cans vs 3 cans vs...), stocks do not seem to have any diminishing marginal value. That is, if I buy 10 shares, I expect to get precisely 10 times the profit than if I bought just 1 share. The value is not diminishing, so why is the demand curve monotonically decreasing? That is because it is not diminishing *for an individual*, but if we look at a market of many individuals, they all have different interpretations of what the marginal value of the stock is. Individual A may interpret the marginal value as \$10, while B sees it as worth \$8, and C sees \$6. All three marginal utility curves would be horizontal, but if we take the market utility, we can see that it is decreasing (e.g. at the price of \$7, a share is attractive to C but not A, B , and at \$9, a share is attractive to B, C but not A). Buying an infinite number of shares is not realistic, so let us assume that each person has \$25 worth to invest.

We can clearly see that the sum of these individual horizontal marginal value functions summed up produces a monotonically decreasing marginal value function and a monotonically decreasing demand curve for the total market.

2. The supply curve is simpler to interpret, since the only supplier is the issuing company (or whatever underwriting investment banks). By the law of supply, we can interpret that if the worth of the company's shares increases, then it would be logical for the company to issue more shares, all else being the same. This interpretation may be too oversimplistic, since we have to account for investor

relations, dilution, and other factors, but it will do for now to justify that the supply curve of a stock is monotonically increasing.

Note that in general, the demand of a company's shares is much more volatile than the supply since there are many ways for the demand to shift, while few for the supply.

1. The demand (not quantity demanded) of a company's shares can be changed from news, world events, production, and such, which occurs often and may even violently shift the outlook of the business.
2. Unlike certain goods that are produced continuously, a company's floating shares will not change unless there is a new issuance or a private investors sells shares at market price. Therefore, supply (not quantity supplied) does not change easily.

Now, let us have the supply and demand curves of a company's share. [From this point on unsure about dynamics of supply/demand curves for stocks] Assume that it is at the equilibrium position, where p_1^* is the current market price (bought and sold) and q_1^* is the quantity demanded and supplied, as balance.

1. If the demand increases, then the shift in the demand curve raises the equilibrium price to p_2^* , which raises the price of the stock. The quantity demanded/supplied also increases to q_2^* , but this desire to increase quantity cannot be met due to other factors. Therefore, we can interpret this case as such: The increase in demand can change the price accordingly, but the increase in desired quantity is offset by other factors (not being able to issue stocks freely).

2. If the supply increases, then this is much simpler to explain. Due to dilution, one stock now represents ownership of a smaller portion of the company, driving the price down. The equilibrium (optimal) quantity demanded and supplied increases due to this higher supply, which is reflected in the reality that there are more more shares issued now.

1.4 Types of Stock Orders

Definition 1.12 (Stock Orders)

The two most common orders one can do is the market order and the limit order.

1. A **market order** just buys or sells securities at the market price. This ensures that the transaction will be completed, but the price at which you buy or sell may not be what you want.
2. A **limit order** buys or sells at least at a certain price. It ensures that you get the price you want for a transaction, but it may not be carried out always.
 - (a) A buy limit order at \$X tells the broker to buy a stock at \$X or lower.
 - (b) A sell limit order at \$x tells the broker to sell a stock at \$ or higher.
3. A **stop loss order** is used to limit an individual's loss or lock in a profit on a stock position.
 - (a) If an investor buys a stock at \$100, they can make a stop loss at \$95. This means that when the stock price reaches \$95, then it will automatically place a market order to sell the stock (the price may not be fulfilled at exactly \$95 due to volatility).
 - (b) If an investor has a short position, on the stock, then they can put a stop loss order at \$105, essentially telling the broker to buy the stock when the price reaches \$105.

In addition to holding a long position, we can **short sell**, or short, a stock. Given that 100 shares of AAPL are each priced at \$100, we can borrow shares from some investor (probably an institutional investor), sell it on the market for \$100, and hope for the price to drop so we can buy it back. This is pretty symmetric to longing a stock, and many hedge funds use a **long-short equity strategy** involving a combination of longs and shorts, but there are additional risks.

1. You must pay additional interest for borrowing stocks.
2. Your potential losses is not bounded.
3. If you have too much unrealized losses as the stock price goes up, then you may not have enough **margin** (cash) in your account to even buy back to stock. To prevent this, your broker may issue a **margin call**, which forces you to buy the stocks back, locking in your loss, unless you add more capital to your account. This margin call may not happen right at the point when your free cash is not enough to buy back all shorted shares. Rather, your brokerage may run some complicated statistical simulations, calculate some confidence interval, and then decide on a threshold that determines whether you will get a margin call.

The third risk is the deadliest, and at worst, you can get **short-squeezed**. Let's explain how this works. Say you and a bunch of other investors shorted GME. GME prices start going up, and it reaches a point where some investors have to buy back the GME shares due to a margin call. The investors buy back the GME at market price, which adds more orders to the limit order book, causing the price to go even higher. This higher price causes more short-sellers to buy back GME due to additional margin calls, causing GME to go even higher, and so on. This positive feedback loop is extremely deadly, killing off many short sellers.

Sometimes, the ethics of short selling are called into question. People who want to ban shorting state that short selling can drive down the stock price, which can be bad because it doesn't spur the economy and reduces optimism in stock markets. Short selling means that stock is being borrowed and sold on the market, increasing supply, and therefore (all else being equal) decreasing price. However, these short sellers keep the stock price more in line with reality, and bad companies are punished by short sellers.

Finally, the entities that drive this short selling are **prime brokers**, which are large financial institutions (usually investment banks) that provide financial management to mainly hedge funds. They act on behalf of the short seller, locating the assets to be sold short for them and providing them with a margin account (which must hold capital to the sum of at least 150% of the value of the initial transaction). They enable hedge funds to borrow large amounts of stocks from institutional investors to short-sell them and allow them to access large amounts of margin from commercial banks. The prime brokerage makes money through commissions. Prime brokers can also loan capital to investors to increase their leverage, and they also provide

financial research and analytics to their clients.

1.5 Dark Pools

The inefficient aspect about markets that they are sensitive to large **block trades**, which are defined to be a trader involving at least 10,000 shares or at least \$200,000 (though they can get much larger). They are usually made by institutional investors and are often privately negotiated in order to prevent market price changes and fluctuations. When an institutional investor would like to make a sell block trade, they can either

1. sell it on the exchange, where it will cause downwards pressure on the price, causing **slippage** (think of the limit order book: this sell order would clear out all buy orders past the sell price) and perhaps affecting the wider market. Even worse, once an order to sell a huge block has been filled, an investor can submit a buy order at a lower price in hopes that the block sell will hit his lowered price (this is an example of front running).
2. sell it privately off an exchange, but finding other parties to buy such a large amount is difficult.

Either way is quite unfavorable. The market impact of a sale of one million shares in Company XYZ could still be sizable regardless of which option the investor chose since it was not possible to keep the identity or intention of the investor secret in a stock exchange transaction.

These investors can trade in **dark pools**, which are privately organized financial exchanges for trading securities, also an **alternative trading system** (ATS). They were created originally to facilitate block trading by institutional investors who did not wish to impact the markets with their large orders. Most importantly, they keep trades anonymous. They allow traders to make block trades without having to publicize who they are, the buy/sell price, or the number of shares traded.

1.6 Market Manipulation

High Frequency Trading operates on the level of 10ms (time for average blink of human eye is 150ms). The way people operate on this level is called **colocation** (the process of renting your servers physically near the market to decrease latency). This process of profiting off of small price changes by fast reselling is called **scalping**.

1. Good: *Increases liquidity (HFTs are always willing to make a market out of you), reduce potential trading costs for individual investors.*
2. Bad: *Front-running orders in front of institutional investors, increase market volatility and systematic risks.*
3. Ugly: *Illegal activities such as **spoofing** (fake orders), that is, rapid placing and cancelling orders to create false sense of supply and demands.*

Market manipulation is a type of market abuse where there is a deliberate attempt to interfere with the free and fair operation of the market.

1. **Stock Bashing**: Creating fake news about a company to drive prices down and get shares for a cheaper price. The perpetrators sometimes work directly for Investor Relations firms who have convertible notes that convert for more shares the lower the bid or ask price is. Thus, the bashers can drive the stock price down by convincing shareholders that they have bought a worthless security.
2. **Pump and Dump**: Misleadingly promoting a company to drive share prices up (the "pump", e.g. with bogus emails to investors). When the stock price reaches a target level, the promoter sells their shares (the "dump").
3. **Spoofing / Layering**: When a trader places a bid or offer on a stock with the intent to cancel before execution, these fake order trick other market participants by creating the false impression of heavy buying or selling pressure. Layering is an advanced form of spoofing with multiple orders that are "layered." For example, let's say that I want to buy stock XYZ, which is priced at \$100. If I wanted to

use layering, I would put a sell order of 100 stocks at \$101, 100 at \$102, and 100 at \$103. An algorithm or trader might see this and believe that there is selling pressure and jump in front of these orders before they go down. They might sell at the market price of \$100, which may bring the price of XYZ a bit lower, to say \$99.95. I can buy at this price now.

4. **Front Running / Tailgating:** This is the practice of entering into a transaction that takes advantage of nonpublic knowledge of a large "block" pending transaction that will influence the price of an underlying security. Say a broker gets an order from a major client to buy 500,000 shares of XYZ Co. Such a huge purchase is bound to drive up the price of the stock immediately, at least in the short term. The broker sets aside the request for a minute and first buys some XYZ stock for their own personal portfolio or through accounts of relatives. Then the client's order is put through. The broker immediately sells the XYZ shares and pockets a profit. This can be used by HFT firms, since with the knowledge of large block buy orders from institutions, they can "buy up" all the orders in the market and sell it at a slightly higher price to the institutions.
5. **Quote Stuffing:** This is the practice of quickly entering and withdrawing a large number of orders in an attempt to flood the market, used by HFT firms. This can create confusion in the market (by filling up bandwidth and increasing latency of the data feed lines) and trading opportunities for high-speed algorithmic traders.

Another illegal act, which isn't market manipulation, is *insider trading*, which refers to a company insider who trades on advanced knowledge of corporate activities.

2 Stocks

Let us introduce some valuation metrics that are used for analyzing a portfolio. We will usually work with some sort of time series of the form $\{X_i\}_{i=0}^n$ (i.e. a discrete-time stochastic process), but if we are only worried about the initial and final price X_0 and X_n , then we will just mention them.

Definition 2.1 (Stock Price)

Given a stock P , we can construct a discrete-time stochastic process $\{P_i\}$, where P_i are random variables.

Definition 2.2 (Dividend)

Given time i, j with $i < j$, the dividend that a stock P pays within time interval $[i, j]$ is the random variable

$$D_{[i,j]}$$

Definition 2.3 (Total Return)

Given stock price $\{P_i\}$, the amount of money you would have made from time i to J is the random variable

$$P_j - P_i + D_{[i,j]}$$

The **total return** during that period is defined

$$R_{[i,j]} = \frac{P_j - P_i + D}{P_i} = \frac{P_j - P_i}{P_i} + \frac{D_{[i,j]}}{P_i}$$

which is the price return plus the dividend rate. If this is a single-step return, i.e. $j = i + 1$, then we can write this as shorthand:

$$R_i = R_{[i-1,i]} = \frac{P_i - P_{i-1}}{P_{i-1}} \approx \ln \left(\frac{X_i}{X_{i-1}} \right) \text{ for } i = 1, \dots, n$$

Sometimes, we refer to **return** as the total return without the dividend payment.

Most of the time, we work in **log returns** as an appropriate approximation of the return. This is mathematically justified since if we fix P_i and assume that P_j is close to P_i , we can take the Taylor expansion of $\ln(P_j)$ to be

$$\ln(P_j) \approx \ln(P_i) + \frac{1}{P_i}(P_j - P_i) \implies \frac{P_j - P_i}{P_i} \approx \ln(P_j) - \ln(P_i) = \ln\left(\frac{P_j}{P_i}\right)$$

Almost always, we will work with log returns and $R_{[i,j]}$ will denote the log return from time i to j . It has its advantages:

1. It is time-additive: If we have prices P_i, P_j, P_k for $i < j < k$, we can see that

$$R_{[i,j]} + R_{[j,k]} = \log\left(\frac{P_j}{P_i}\right) + \log\left(\frac{P_k}{P_j}\right) = \log\left(\frac{P_k}{P_i}\right) = R_{[i,k]}$$

2. Symmetricity: It is well known that a stock going down 50% and then going up 50% does not return the stock to its original price, despite it "looking" like it did. This effect is killed when looking at log returns. If $P_j = P_k(1 - k)$ for $0 < k < 1$, then we know that it must scale up by a factor of $\frac{1}{1-k} \neq 1 + k$ to get the original price. Indeed, it is clearly the case that

$$\log(1 - k) + \log(1 + k) = \log(1 - k^2) < 0$$

and in fact is always less than 0 (so we always lose money). This is due to the concavity of this function.

3. It focuses on relative change, which is typically invariant on the underlying price of the stock.

These properties allow us to focus on the returns to calculate our metrics.

Definition 2.4 (Expected Return)

The **expected return** of a stock from time i to j is simply the expected value

$$\mathbb{E}[R_{[i,j]}] = \mathbb{E}\left[\frac{P_j - P_i}{P_i}\right] \approx \mathbb{E}[\log(P_j) - \log(P_i)]$$

Definition 2.5 (Stock Volatility)

Given a stock P , its return $R_{[i,j]}$ is a random variable. Its standard deviation is called the **volatility**.

$$\sigma = \sqrt{\text{Var}(R_{[i,j]})}$$

If we do have data on the stock $\{P_i\}_{i=0}^n$ and its log returns $\{R_i\}_{i=1}^n$, the volatility can be estimated simply by taking the sample standard deviation of this data

$$\sigma = \sigma(\{R_i\}_{i=1}^n) = \sqrt{\frac{1}{n} \sum_{i=1}^n (R_i - \mu)^2} \text{ where } \mu = \frac{1}{n} \sum_{i=1}^n R_i$$

Definition 2.6 (Sharpe Ratio)

The **Sharpe ratio** is a measurement of risk-adjusted return. Given that you have some stock price

with total return R and volatility σ , the Sharpe ratio is defined as the random variable

$$S = \frac{R - R_f}{\sigma}$$

where R_f is risk-free return (e.g. the return you earn on U.S. Treasury bonds), which can be considered as a constant random variable. Sometimes, R_f may not be constant and may be some time-series data itself.

The Sharpe ratio is one of the most widely used metrics, and it is usually based on an annual horizon. While it is straightforward to compute the annual returns, it is more difficult to compute the annual volatility of a stock because it is sensitive to the time scale (i.e. computing it using daily data will result in much higher volatility than computing in minutely data). In practice, people follow the Square-root-of-Time rule, which takes the daily volatility by a factor of square root of 260, which is approximately the number of trading days in a year. Therefore, the invariant annual Sharpe ratio is

$$S = \frac{R - R_f}{\sigma\sqrt{260}} \quad (1)$$

2.1 Momentum Strategies

Momentum strategies can be divided into **momentum trending**, which bets that the stock price will continue following the trend, and **momentum reversing**, which bets that the stock price will revert back to some mean.

2.1.1 Moving Averages

The simple moving average and the exponential moving averages represent where the stock's price is at average.

Definition 2.7 (Simple Moving Average)

Let us have some stock price $\{P_i\}_{i=0}^N$ and fix some lookback parameter L . Then, the L -period **simple moving average (SMA)** of the stock is the average of prices of the past L periods, $\{S_i\}_{i=L-1}^N$, where

$$S_i = \frac{1}{L} \sum_{j=i-L+1}^i P_j$$

Definition 2.8 (Exponential Moving Average)

We can build momentum strategies by comparing two different MAs of lookback periods $L_1 < L_2$. We can compare the current price to the moving averages, but the current price can be thought of as the 1-period moving average anyways. The L_2 -MA is thought of as the long term trend of the stock, while the L_1 -MA is the short-term trend. The follow are essentially MA strategies.

1. Momentum Trending:

- (a) If the L_1 -MA is above the L_2 -MA, then the stock has momentum upwards. \implies Long.
- (b) If L_1 -MA is below the L_2 -MA, then the stock has momentum downwards. \implies Short.

2. Momentum Reversing:

- (a) If the L_1 -MA is above the L_2 -MA, then the stock has momentum upwards. \implies Short.
- (b) If L_1 -MA is below the L_2 -MA, then the stock has momentum downwards. \implies Long.

2.1.2 Bollinger Bands

Definition 2.9 (Bollinger Bands)

Let us have some stock price $\{P_i\}_{i=0}^N$ and fix some lookback parameter L , along with some z -score Z . We compute the standard deviation of the prices P_i in the past L periods to get $\{\sigma_i\}_{i=L-1}^N$.

1. The **middle band** is defined to be the L -period SMA, which we will call

$$\{\mathcal{M}_i\}_{i=L-1}^N$$

2. The **upper band** is defined to be the band that is Z standard deviations above the middle band.

$$\{\mathcal{U}_i\}_{i=L-1}^N = \{\mathcal{M}_i + Z\sigma_i\}_{i=L-1}^N$$

3. The **lower band** is defined to be the band that is Z standard deviations below the middle band.

$$\{\mathcal{L}_i\}_{i=L-1}^N = \{\mathcal{M}_i - Z\sigma_i\}_{i=L-1}^N$$

Now the algorithm for Bollinger bands is very simple.

1. In a momentum following case, if P_i crosses below \mathcal{L}_i , we short, and if P_i crosses above \mathcal{U}_i , we long.
2. In a momentum reversing case, if P_i crosses below \mathcal{L}_i , we long, and if P_i crosses above \mathcal{U}_i , we short. The upper band acts as a resistance level, and the lower band acts as a support level.

2.1.3 Relative Strength Index

The relative strength index indicates the momentum or lack of it.

Definition 2.10 (Relative Strength Index)

Let us have some stock price $\{P_i\}_{i=0}^N$. Let us define the period changes as $\{D_i\}_{i=1}^N$ with $D_i = P_i - P_{i-1}$. Then, the total gain and total loss can be defined as

$$D_{\text{gain}} = \sum_{D_i > 0} |P_i - P_{i-1}|, \quad D_{\text{loss}} = \sum_{D_i < 0} |P_i - P_{i-1}|$$

Then, the **relative strength index (RSI)** is defined to be

$$RSI = 100 \frac{D_{\text{gain}}}{D_{\text{gain}} + D_{\text{loss}}}$$

which ranges in $[0, 100]$, where 0 is extremely bearish and 100 is extremely bullish. Roughly, the RSI being 30 means that for every 1 increase in a period, there are 2 decreases in other periods. The RSI being 70 means that for every 1 decrease, there are 2 increases.

The algorithm is quite simple:

1. In a momentum following case, if the RSI is below 30, we short, and if the RSI is above 70, we long.
2. In a momentum reversing case, if the RSI is below 30, we long, and if the RSI is above 70, we short.

2.1.4 Determining Momentum Trending or Reversing

Now how can we quantitatively decide whether we should use a momentum trending or reverting strategy? We can measure this behavior of a stock by looking at its autocorrelation.

Definition 2.11 (Autocorrelation)

Let us have some stock price $\{P_i\}_{i=0}^N$ and fix some lookback parameter L . We construct a lagged version $\{P_i\}_{i=0}^{N-L}$ and compute the correlation of this lagged time series with the original.

$$\text{Corr}(\{P_i\}_{i=0}^{N-L}, \{P_i\}_{i=L}^N)$$

is called the L -period **autocorrelation** of the stock price.

We can determine which strategy to use as follows. Let us assume that L is small.

1. If this autocorrelation is high (near 1), then this indicates that if the stock moves in a certain direction, it is likely to move in that same direction L periods later. So we should use a momentum following strategy.
2. If it is negative (near -1), it indicates that if the stock moves in a certain direction, it is likely to move in the opposite direction L periods later. So we should use a momentum reverting strategy.

Trend following stocks tend to be growth stocks, while trend reversing ones are the traditional conservative companies.

2.2 Pairs Trading**2.2.1 Naive Approach**

Intuitively, pairs trading takes two stocks of very similar companies and bets that they will rise and fall together. If one rises and the other falls, then we can long the one that falls and short the one that rises, ultimately betting on the way that they will converge. To do this, take two sets of stock prices

$$\{P_i\}_{i=0}^N \text{ and } \{Q_i\}_{i=0}^N$$

We first talk about the naive approach, which assumes that if P rises by 5%, then Q will also rise by 5%. Beginners just look at their common ratios $\{P_i/Q_i\}_{i=0}^N$ and calculate whether this time series diverge or not. Remember that this is not symmetric, so we must log both of them and look at the log of the quotient, i.e. the difference of the logs.

$$\left\{ \log \left(\frac{P_i}{Q_i} \right) \right\}_{i=0}^N = \{ \log(P_i) - \log(Q_i) \}_{i=0}^N$$

If this time series diverges too much from its average, then we can long and short accordingly. This is another way of saying that the time series of returns are

However, this model is too simplistic, since we are limited by the assumption that if P rises by 5%, then Q will also rise by the same 5%. Companies P and Q may use similar supply chains, but perhaps P is more dependent on it than Q . Therefore, if there are supply chain problems, then the effect on P may be say, twice as much as that on Q . So, if P goes down by 5%, then Q may go down by 2.5%.

2.2.2 Sophisticated Pairs Trading

Ultimately, our basis assumption is that the returns are linearly correlated in the following relationship.

$$\frac{\Delta P}{P} = \beta \frac{\Delta Q}{Q} \iff \log(P_j) - \log(P_i) = \beta (\log(Q_j) - \log(Q_i))$$

This results in the model

$$\log(P) = \beta \log(Q) + \alpha + \epsilon$$

which can be seen to be equivalent because taking the change over time $[i, j]$ on both sides gives

$$\Delta \log(P) = \beta \Delta \log(Q) + \Delta \epsilon \iff \frac{\Delta P}{P} = \beta \frac{\Delta Q}{Q} + \Delta \epsilon$$

So, if we look at

$$\{\epsilon_i\}_{i=0}^n = \{\log(P_i) - \beta \log(Q_i) - \alpha\}_{i=0}^n$$

we expect this to be a 0-mean time series. Let the standard deviation be $\sigma = \sigma(\{\epsilon_i\}_{i=0}^n)$ and let us fix some Z-score threshold. Then

1. If $\epsilon_i > Z\sigma$, then short P and long Q .
2. If $\epsilon_i < -Z\sigma$, then long P and short Q .

2.2.3 Long/Short Market Weights

But how much should we long or short? Let's look at a couple scenarios:

1. If $\beta = 1$, and we shorted \$99 of P and long \$1 of Q , then a 5% rise in P would result in 5% rise in Q , but since we shorted much more of P , we would have a net loss. To mitigate this risk, we should have a weight of $P : Q = 1 : 1$.
2. If $\beta = 10$, and we shorted equally \$50 of P and long \$50 of Q , then a 10% rise in P would result in a 1% rise in Q . But since we had equal weights in P and Q , this scenario would cause 10 times more losses in P than gains in Q , resulting in a net loss. To mitigate this risk, we should have a weight $P : Q = 1 : 10$.

So, we need to be careful of setting the ratio of our market weights of the stocks P and Q :

$$\lambda = \frac{MV_Q}{MV_P}$$

Intuitively, we can see that our ratio should be $1 : \lambda = 1 : \beta$, i.e. $\lambda = \beta$, but let's formalize this with some mathematical derivation. Our portfolio value is

$$V = MV_P + MV_Q$$

where $MV_P = n_P P$ and $MV_Q = n_Q Q$, where n_P, n_Q are the number of shares of P, Q . If we are longing P and shorting Q , then $n_P > 0$ and $n_Q < 0$. Then, our change in portfolio value V is

$$\begin{aligned} \Delta V &= \Delta MV_P + \Delta MV_Q \\ &= MV_P \left[\frac{\Delta MV_P}{MV_P} + \frac{MV_Q}{MV_P} \frac{\Delta MV_Q}{MV_Q} \right] \\ &= MV_P \left[\frac{\Delta P}{P} + \lambda \frac{\Delta Q}{Q} \right] \\ &= MV_P \left[\beta \frac{\Delta Q}{Q} + \Delta \epsilon + \lambda \frac{\Delta Q}{Q} \right] \\ &= MV_P \left[(\beta + \lambda) \frac{\Delta Q}{Q} + \Delta \epsilon \right] \end{aligned}$$

Therefore, our change in portfolio value depends on the terms in the last equation. We don't want the change ΔQ to have any effect on the performance, so we set $\lambda = -\beta$, ultimately resulting in

$$\Delta V = MV_P \Delta \epsilon$$

and now our performance is purely dependent on $\Delta \epsilon$. We would like ΔV to be positive, so if we are longing P , i.e. $MV_P > 0$, then we want $\Delta \epsilon$ to also be positive. Likewise, if we are shorting P , then $MV_P < 0$ and so we want $\Delta \epsilon < 0$.

2.2.4 Choosing Correct Stocks

So, how do we ensure that $\Delta\epsilon$ behaves this way? Remember that $\{\epsilon_i\}$ is 0-mean time series. However, we want to impose the additional condition that it is *mean-reverting* as well. That is, we don't want it to diverge or oscillate too frequently ϵ_i , since if it did then there is the risk of $\{\log(P_i) - \beta \log(Q_i) - \alpha\}_{i=0}^n$ swinging too widely, resulting in losses. In other words, if $\epsilon_i > 0$, then we want $\Delta\epsilon_{i+1} = \epsilon_{i+1} - \epsilon_i < 0$, and if $\epsilon_i < 0$, then $\Delta\epsilon_{i+1} > 0$, so that the ϵ_i 's tend to "go back towards 0." More formally, we can plot all ϵ_{i-1} 's with the $\Delta\epsilon_i$'s, and look at a potentially linear relationship

$$\Delta\epsilon_i = \alpha\epsilon_{i-1} + \xi_i$$

To be mean reverting, we want to test that $\alpha < 0$ with adequate statistical significance, i.e. with p-value 5%. By looking at not just the previous ϵ_{i-1} but also the last p ϵ_i 's we can develop the general linear relationship

$$\Delta\epsilon_i = \xi_i + \sum_{j=1}^p \alpha_j \epsilon_{i-j}$$

This is called the **Augmented Dickey Fuller (ADF)** test, which tells us whether a time series is mean-reverting or not.

2.2.5 Entry and Exit Points

3 Stock Portfolio Analysis

We will define a portfolio as a collection of K stocks with prices labeled as a time series data

$$\{P_{1,i}\}_{i=1}^N, \{P_{2,i}\}_{i=1}^N, \dots, \{P_{N,i}\}_{i=1}^N \quad (2)$$

with one-step returns $\{R_{k,i}\}_{i=1}^N$ for each $k = 1, \dots, K$ and total return over the period $[0, N]$ as R^k . For simplicity, let us assume that we buy all stocks at time 0 and hold until time N , and so we can consider a one-period market with $\{P_{k,0}, P_{k,1}\}$ for $k = 1, \dots, K$ and corresponding returns

$$\{R_k\} = \{\log(P_{k,1}) - \log(P_{k,0})\} \quad (3)$$

all random variables.

Definition 3.1 (Market Value of Portfolio)

The **market value of a portfolio** $\{P_1, \dots, P_K\}$ is the random variable

$$V = \sum_k MV_k = \sum_k n_k P_k \text{ which is } \sum_k n_k P_{k,0} \text{ at time } t = 0 \quad (4)$$

The market weights for each stock is determined as

$$w_k = \frac{MV_k}{V} \quad (5)$$

where $\sum w_k = 1$. We will denote $\mathbf{w} = (w_1, \dots, w_K)$. If we allow unlimited shorting, then the possible values of \mathbf{w} are $\{\mathbf{w} \in \mathbb{R}^K \mid \mathbf{w} \cdot \mathbf{1} = 1\}$, but if we only allow all-long positions, then this domain reduces to $\{\mathbf{w} \in \mathbb{R}^K \mid \mathbf{w} \cdot \mathbf{1} = 1, 0 \leq w_k \leq 1\}$.

Definition 3.2 (Portfolio Return)

The **portfolio return vector** is the random K vector of returns $\mathbf{R} = (R_1, \dots, R_K)^T$, which may be correlated. We can take its expectation by taking the component expectations over the sample space w , or by integrating the component mappings $e_k : \mathbb{R}^K \rightarrow \mathbb{R}$ over the measure λ induced by \mathbf{R}

$$\mathbb{E}[\mathbf{R}] := \begin{pmatrix} \mathbb{E}[R_1] \\ \vdots \\ \mathbb{E}[R_K] \end{pmatrix} = \begin{pmatrix} \mathbb{E}_\lambda(e_1) \\ \vdots \\ \mathbb{E}_\lambda(e_K) \end{pmatrix} \quad (6)$$

The **portfolio return** is defined as the random variable

$$R = \mathbf{w}^T \mathbf{R} = \sum_{k=1}^K w_k R_k \quad (7)$$

i.e. the weighted sum of the individual total returns of the stocks. The **expected return** of the portfolio is simply

$$\mathbb{E}[R] = \sum_{k=1}^K w_k \mathbb{E}_\lambda[R_k] \quad (8)$$

We can estimate this by sampling the historical returns of the k th stock $R_{k,i}$ of the required length for each stock and then estimating its mean. That is, for each k ,

$$R_k \approx \hat{R}_k = \frac{1}{n} \sum_{i=1}^n R_{k,i} \quad (9)$$

Definition 3.3 (Portfolio Variance, Volatility)

The **covariance matrix** of the portfolio is defined as the covariance matrix of the random vector of returns \mathbf{R} .

$$\mathbf{\Sigma} = \text{Cov}(\mathbf{R}) := \begin{pmatrix} \text{Var}(R_1) & \dots & \text{Cov}(R_1, R_K) \\ \vdots & \ddots & \vdots \\ \text{Cov}(R_K, R_1) & \dots & \text{Var}(R_K) \end{pmatrix} \quad (10)$$

We can estimate this by sampling the one-period historical returns R_k and computing the sample variance/covariance

$$\sigma_{k_1 k_2} = \text{Cov}(\{R_{k_1,i}\}, \{R_{k_2,i}\}) \quad (11)$$

The **portfolio variance** is simply the variance of R .

$$\text{Var}(R) = \mathbf{w}^T \mathbf{\Sigma} \mathbf{w} \approx \sum_{k_1, k_2=1}^K w_{k_1} w_{k_2} \sigma_{k_1, k_2} \quad (12)$$

and the **portfolio volatility** is simply the standard deviation of R

$$\sqrt{\text{Var}(R)} \quad (13)$$

Definition 3.4 (Alpha)

Alpha is a measure of performance. The **alpha** of a security/portfolio with return R_p compared to

some market return R_m is defined as

$$\alpha := \mathbb{E}[R_p - R_m] = \mathbb{E}[R_p] - \mathbb{E}[R_m] \quad (14)$$

If we are given samples of returns $\{R_{p,i}\}$ and $\{R_{m,i}\}$, then we can estimate the α simply as

$$\hat{\alpha} = R_p - R_m = \sum_{k=1}^{j-i} R_{p,i+k} + \sum_{k=1}^{j-i} R_{m,i+k} \quad (15)$$

Definition 3.5 (Beta)

Beta is a measure of volatility. The **beta** of a stock compared to some market is defined

$$\beta := \rho_{pm} \frac{\sigma_p}{\sigma_m} = \frac{\text{Cov}(R_p, R_m)}{\text{Var}(R_m)} \quad (16)$$

where ρ_{pm} is the correlation between R_m and R_f and σ represents the volatility of returns. If we are given samples of returns $\{R_{p,i}\}$ and $\{R_{m,i}\}$, then we can estimate the beta using the sample correlation and standard deviation:

$$\hat{\beta} = \hat{\rho}_{pm} \frac{\hat{\sigma}_p}{\hat{\sigma}_m} = \rho(\{R_{p,i}\}, \{R_{m,i}\}) \frac{\sigma(\{R_{p,i}\})}{\sigma(\{R_{m,i}\})} \quad (17)$$

If a stock has beta value of 1, then its price activity is strongly correlated with the market (or the benchmark B_j). A $\beta < 1$ means that the security is less volatile than the market, and $\beta > 1$ means more volatile. A negative β indices that the stock is inversely correlated with the market.

3.1 Markowitz Portfolio Theory - Mean Variance Portfolio

Consider a one-period market with K independent securities which have identical expected returns and variances, i.e. consider $\{P_{k,0}, P_{k,1}\}$ for $k = 1, \dots, K$. Then, the returns

$$R_k = \log(P_{k,1}) - \log(P_{k,0})$$

are random variables such that $\mathbb{E}[R_k] = \mu$ and $\text{Var}(R_k) = \sigma^2$. Let w_k denote the fraction of wealth invested in the k th security. Now consider two portfolios

1. Portfolio A: 100% invested in stock 1 so that $w_1 = 1$ and $w_k = 0$ for $k = 2, \dots, K$
2. Portfolio B: An equi-weighted portfolio so that $w_k = \frac{1}{K}$ for all k .

Let R_A and R_B denote the portfolio returns of A and B. Then, we have

$$\begin{aligned} \mathbb{E}[R_A] &= \mathbb{E}[R_B] = \mu \\ \text{Var}(R_A) &= w_1 \text{Var}(R_1) = \sigma^2 \\ \text{Var}(R_B) &= \text{Var}\left(\frac{1}{K} \sum_{k=1}^K R_k\right) = \frac{1}{K^2} \sum_{k=1}^K \text{Var}(R_k) = \sigma^2/K \end{aligned}$$

which means that even though the expected returns of portfolios A and B are the same, the volatility of B is much less than that of A, making it much more advantageous. We can clearly see that the Sharpe ratio of A is μ/σ (assuming the risk-free return is 0), but the Sharpe ratio of B is $\mu\sqrt{K}/\sigma$, which means that as we increase our number of independent stocks K , the ratio goes up by a factor of \sqrt{K} .

3.1.1 Efficient Frontier without Risk-Free Asset

Given a portfolio of stocks $\{P_1, \dots, P_K\}$ with corresponding return vector $\mathbf{R} = (R_1, \dots, R_K)$, let us take its expected value $\boldsymbol{\mu} = \mathbb{E}[\mathbf{R}]$ and covariance matrix $\boldsymbol{\Sigma} = \text{Cov}(\mathbf{R})$. Its portfolio return is $R = \mathbf{w}^T \mathbf{R}$. We will assume that we must invest all of our cash into something, which will manifest in the constraint equation $\mathbf{w}^T \mathbf{1} = 1$.

Definition 3.6 (Efficient Frontier without Risk-Free Asset)

We would like to construct a risk-return efficient portfolio (by determining the w_k 's) so that it has the highest return for the same amount of risk, or the lowest risk for some amount of return. That is, letting $R_{\mathbf{w}}$ be the return of a portfolio with weight \mathbf{w} , we would like to find

$$\arg \min_{\mathbf{w} \in \mathbb{R}^K} \text{Var}(R_{\mathbf{w}}) = \arg \min_{\mathbf{w} \in \mathbb{R}^K} \frac{1}{2} \mathbf{w}^T \boldsymbol{\Sigma} \mathbf{w}$$

subject to the constraint equations $\mathbf{w}^T \boldsymbol{\mu} = p$ and $\mathbf{w}^T \mathbf{1} = 1$, where p is our target portfolio returns. The solution to this optimization problem is called the **Markowitz efficient frontier**, which traces out a hyperbola of the form

$$\sigma_R^2 = Ap^2 + Bp + C$$

if we get rid of the ω parameter. Here we randomly sample a bunch of \mathbf{w} 's from $[0, 1]^K$ (subject to the constraints, of course), construct the return of the portfolio $R_{\mathbf{w}}$, and then plot the points $(\mathbb{E}[R], \text{Var}(R))$. We can see that none of the points ever cross the frontier.

Note that this efficient portfolio allows us to have unlimited short positions, which may or may not be realistic. If we wanted to work only with all-long portfolios, then we would impose the nonlinear restrictions

$$0 \leq w_k \leq 1 \text{ for } k = 1, \dots, K$$

which would need to be solved numerically, possibly using nonlinear models.

3.1.2 Efficient Frontier with Risk-Free Asset

If we include a risk-free asset such as cash C with risk-free return R_f to the portfolio $\{P_1, \dots, P_K\}$, then we slightly modify our equations. By definition, the risk-free asset has volatility $\sigma_0 = 0$ and its weight must be equal to $w_f = 1 - \sum_{k=1}^K w_k$, so we still want to minimize

$$\sigma^2 = \frac{1}{2} \mathbf{w}^T \boldsymbol{\Sigma} \mathbf{w}$$

subject to constraint equations

$$R_f \left(1 - \sum_{k=1}^K w_k \right) + \sum_{k=1}^K w_k R_k = R$$

When we allow our portfolio to include the risk-free security, the efficient frontier becomes a straight line that is tangential to the risky efficient frontier and with a y -intercept equal to the risk-free rate.

We can include other linear portfolio constraints, such as no-borrowing, no-short sales, or certain sector constraints. While analytic solutions are generally no longer available, the resulting problems are easy to solve numerically.

3.2 Capital Asset Pricing Model

Let us have some stock P with random variable of return $R_p = R_{P,[i,j]}$ and the market M with random variable of return $R_m = R_{M,[i,j]}$, both within period $[i, j]$. There may be some sort of risk-free return r_f available (e.g. U.S. treasury bonds), so we can observe the returns of these two assets past the risk-free return by considering the joint distribution

$$(R_p - r_f) \times (R_m - r_f) \quad (18)$$

This may or may not be correlated, but the capital asset pricing model shows that there exists a linear relationship between the expected values of these two distributions. The central insight of the CAPM is that in equilibrium the riskiness of an asset is not measured by the standard deviation of its return but by its beta.

Theorem 3.1 (CAPM)

Now let $\bar{R}_m = \mathbb{E}[R_m]$ denote the expected return of the market, and $\bar{R} = \mathbb{E}[R]$ denote the expected return of a security or portfolio. Then, the **capital asset pricing model (CAPM)** asserts that there exists a linear relationship

$$\bar{R} = r_f + \beta(\bar{R}_m - r_f) \quad (19)$$

where r_f is the risk-free rate.

Proof.

Let us consider a portfolio of weights α and $1 - \alpha$ on the risky security and market portfolio, respectively. Let R_α denote the random return of this portfolio as a function of α . We then have

$$\begin{aligned} \mathbb{E}[R_\alpha] &= \alpha \bar{R} + (1 - \alpha) \bar{R}_m \\ \text{Var}(R_\alpha) &= \alpha^2 \text{Var}(R) + (1 - \alpha)^2 \text{Var}(R_m) + 2\alpha(1 - \alpha) \text{Cov}(R, R_m) \end{aligned}$$

Note that as α varies, the mean and standard deviation $(\mathbb{E}[R_\alpha], \text{Var}(R_\alpha))$ trace out a curve in \mathbb{R}^2 that cannot cross the efficient frontier, as shown in the dotted line.

At $\alpha = 0$, the slope of this curve must equal the slope of the capital market line. The slope of the α -curve (where $\sigma(R_\alpha) = \sqrt{\text{Var}(R_\alpha)}$) is

$$\begin{aligned} \left. \frac{d\mathbb{E}[R_\alpha]}{d\sigma(R_\alpha)} \right|_{\alpha=0} &= \left. \frac{d\mathbb{E}[R_\alpha]}{d\alpha} \middle/ \frac{d\sigma(R_\alpha)}{d\alpha} \right|_{\alpha=0} \\ &= \left. \frac{\sigma(R_\alpha)(\bar{R} - \bar{R}_m)}{\alpha\sigma(R) - (1-\alpha)\text{Var}(R_m) + (1-2\alpha)\text{Cov}(R, R_m)} \right|_{\alpha=0} \\ &= \frac{\sigma(R_m)(\bar{R} - \bar{R}_m)}{-\text{Var}(R_m) + \text{Cov}(R, R_m)} \end{aligned}$$

The slope of the capital market line is $(\bar{R}_m - r_f)/\sigma(R_m)$, and equating the two

$$\frac{\sigma(R_m)(\bar{R} - \bar{R}_m)}{-\text{Var}(R_m) + \text{Cov}(R, R_m)} = \frac{\bar{R}_m - r_f}{\sigma(R_m)} \quad (20)$$

gives the result.

4 Forward Contracts

Definition 4.1 (Derivatives)

A **derivative** is a financial instrument whose value depends on (is *derived* from) the value of some other, more basic, underlying variable. Essentially, given some stochastic process X_t describing some variable, the derivative is some function

$$Y_t = g(X_t) \quad (21)$$

The reason that we say an underlying *variable* is that it includes real assets (e.g. property), financial assets (e.g. stocks), indices (stock, inflation, or housing price index), or an event (e.g. weather, or the amount of rainfall in a given season to hedge against a bad winter). Therefore, these variables can be anything, like the number of people attending a fair, which may be an indicator of the profit of the fair or some catastrophic event, and we can derive value out of that event. Therefore, the variable does not necessarily have to be an asset.

Example 4.1 (Stock Derivative)

For example, a stock option is derived from the value of the stock, which itself is derived from the value of the underlying company. We will see more specific examples of this later.

Example 4.2 (Weather Derivatives)

A weather derivative can have payout of $g(S_T)$, where

$$g(S_T) = \mathbb{1}\{S_T > 50\} = \begin{cases} \$1 & \text{if } S_T > 50 \\ 0 & \text{if else} \end{cases} \quad (22)$$

where S_T is the total snowfall in inches during the year up to $T = 1$. Note that both S_T and $g(S_T)$ are random variables whose value is unknown until $T = 1$.

Definition 4.2 (Payoff Graph, Profit-Loss Diagram)

To see the dependency between the underlying and the derivative, it helps to plot g , known as the **payoff graph**. The x -axis tells you the value of the underlying asset, and the y -axis tells you the payoff that a certain buyer or seller will make given the price of the underlying asset. A **profit-loss diagram** is the same thing but it accounts for the premium paid on a contract. This is important for options since the buyer pays a premium to enter the contract, but doesn't make a difference for forward or future contracts.

Now we will see the most common type of derivative: the forward contract.

Definition 4.3 (Forward Contracts)

Forward contracts are simply contracts between two parties to buy or sell an asset at a future date for a price agreed upon today.

1. T is the time until delivery, usually in years. This is fixed per contract.
2. K is the delivery price. This is also fixed per contract.
3. S_t is the spot price of the asset at time $t \in [0, T]$.
4. $V_K(t, T)$ is the value of the contract at current time $t \leq T$ of being long a forward contract with delivery price K and maturity T . This will vary over time.
5. $P(t, T)$ is the price of the forward contract at time t with maturity T . This is the price that you pay to enter the contract.

Example 4.3 (Red Sox)

If I buy the Boston Red Sox regular season wins at 90, in size one dollar per won, I have a long forward position with delivery price of 90. If the Red Sox wins 100 games I make \$10, and if they have 81 wins I lose \$9. The payout is $S_T - K$ where S_T is the number of wins.

4.1 Primary Markets and Types of Forwards**Example 4.4 ()**

We have a forward contract that agrees to buy/sell an asset for $K = \$100$ in $T = 3$ months. Then, the buyer and seller have the following payoff graphs.

Figure 1

We can see from the following that this is a zero-sum game. Therefore, *no wealth* is created or destroyed in a forward contract, it is only transferred. Since there was no cost to enter the contract, the profit is really a linear relationship between the price of the underlying asset. This is unlike options, where there is a cost to enter since the buyer or seller has the *right*, but not the obligation to buy/sell the asset. This right puts an extra premium on the option that you must pay for.

Definition 4.4 (Settlement)

If a contract is **physically settled**, it means that the buyer actually pays K and receives the asset at time T . However, some forwards are **cash settled**, meaning one simply receives (pays if negative) the amount $S_T - K$ at time T . The profit/loss is the same, but there are some key differences.

1. A cash settled forward has no further exposure to the asset price since you're just receiving the difference in cash. However, a physically settled contract implies that the buyer now owns the asset at T , which continues to have exposure to asset price movements.

4.2 Forward Contract Valuation

Now let's talk about how you would value a forward.

Definition 4.5 (Value at Maturity, Payout)

Since the party that longs the forward contract must pay K at T to buy an asset which is worth S_T , the value of the contract at T is

$$V_K(T, T) = S_T - K \quad (23)$$

This is referred to as the **value at maturity** or the **payout** of the contract.

Definition 4.6 (Forward Price)

The **forward price** $F(t, T)$ at the current time $t \leq T$ is the delivery price K such that

$$V_K(t, T) = 0 \implies V_{F(t, T)}(t, T) = 0 \quad (24)$$

That is, it is the price that makes the contract have zero value at the current time. By definition, it must be the case that $F(T, T) = S_T$ since to buy an asset at T for the price $F(T, T)$ is the same as buying the asset at the spot price S_T .

Since the forward price tells you what the value of the underlying asset K should be at time T for the contract to have no value, it is a good indicator of the actual value of the contract. When the forward is

created, it has no intrinsic value, but as time goes on, the value of the contract changes as the spot price changes.

Example 4.5 ()

Suppose that a stock which pays no dividends always has price 100 and interest rates are always 0. Then

1. $F(t, T) = 100$ since if you had the right to buy the stock at 100 at any time T , then this would be the same as buying the stock at the spot market, but it is always 100 in the spot market. So the value of this contract must be 0 for all T .
2. $V_K(t, T) = 100 - K$ since if you have the right to buy the stock at K in time T , the spot price will always be worth 100 so you're really gaining $100 - K$. Therefore the value of this contract must be $100 - K$ for all T .

4.3 Forward Prices

Theorem 4.1 (Forward Price of No Income Asset)

For an asset paying no income (e.g. a stock with no dividends), the forward price is

$$F(t, T) = S_t e^{r(T-t)} \implies F(0, T) = S_0 e^{rT} \quad (25)$$

Proof.

Replication. At current time t , let's take two portfolios.

1. A: Consists of one unit of the underlying stock.
2. B: One long forward contract with delivery price K , plus $Ke^{-r(T-t)}$ of cash.

At time T , B can invest the cash at the risk free rate r and get K cash. Then, it executes the forward contract at K to get one stock. Therefore, at time T , both portfolios are worth S_T and the values of both portfolios at time t must also be the same. This is called the *replication proof*.

$$S_t = V_K(t, T) + Ke^{-r(T-t)} \implies V_K(t, T) = S_t - Ke^{-r(T-t)} \quad (26)$$

We want to find the value of K such that the value of the contract is 0. Therefore,

$$0 = S_t - Ke^{-r(T-t)} \implies K = S_t e^{r(T-t)} \quad (27)$$

Proof.

No Arbitrage. Another way to prove this is with the **No-arbitrage principle**. What we do is assume that the forward value is above or below our stated value, and prove that under these assumptions there is an arbitrage opportunity.

1. Assume that $F(t, T) < S_t e^{r(T-t)}$. Then, you can buy a forward contract at delivery price $K = F(t, T)$ for free. You can also short the underlying stock at S_t and invest the proceeds at the interest rate r . At time T , you can take your money, which is now worth $S_t e^{r(T-t)}$ and execute the contract by buying one share of the stock for $K = F(t, T)$. This leaves you with no stocks and money of $S_t e^{r(T-t)} - F(t, T) > 0$ by assumption, and you have an arbitrage opportunity.
2. Assume that $F(t, T) > S_t e^{r(T-t)}$. Then, you can sell a forward contract at delivery price $K = F(t, T)$ for free. I borrow S_t money at the interest rate r and buy a stock. At time T , I sell the stock at $F(t, T)$ and also must pay back from who I borrowed at a rate of $S_t e^{r(T-t)}$. Therefore, this leaves me with a net gain of $F(t, T) - S_t e^{r(T-t)} > 0$ by assumption, and I have an arbitrage opportunity.

Therefore, since I have an arbitrage opportunity, it must be the case that $F(t, T) = S_t e^{r(T-t)}$.

Intuitively, with the no arbitrage strategy, we can see that if the forward price is too high relative to the stock price S_t , we buy the stock now and sell the contract (sell the stock forward at the higher price). If the forward price is too low, then we sell the stock now and buy the contract (buy the stock forward at the cheaper price).

Corollary 4.1 (Dependence on Forward Price)

The forward price is only dependent on the current underlying price S_t , the interest rate r , and the time to maturity $T - t$. Counterintuitively, it does not depend on the growth rate, the standard deviation, or any distributional assumptions of S_T . Furthermore, any two assets which pay no income and which have the same spot price S_t will have the same forward price regardless of any views about their future movements.

4.4 Forward Price of Income Assets

However, this is unrealistic in a few things. It first does not account for dividends, the cost of storage, or the cost of carry.

Theorem 4.2 (Forward Price of Income Asset)

Suppose an asset pays a known amount of income (e.g. dividends, coupons, rent) during the life of the forward contract and the present value at t of the income is I . Then,

$$F(t, T) = (S_t - I)e^{r(T-t)} \quad (28)$$

Proof.

Replication. Let us have two portfolios.

1. A: Consists of one unit of the underlying stock.
2. B: Consists of one long forward contract with delivery price K , plus $Ke^{-r(T-t)} + I$ of cash.

Then, B will invest the cash at the risk free rate r and get $K + Ie^{r(T-t)}$ cash. Then it uses K to buy the underlying stock, ending up with $Ie^{r(T-t)}$ in cash and one unit of stock. A, by owning the stock throughout the span, also receives I of cash (present value), which is equal to $Ie^{r(T-t)}$ worth at time T . Therefore, the two portfolios are equal at time T and therefore must be equal at time t .

$$S_T + Ie^{r(T-t)} = V_K(T, T) + K + Ie^{r(T-t)} \implies S_t = V_K(t, T) + Ke^{-r(T-t)} + I \quad (29)$$

Therefore, we can solve for the forward price by setting $V_K(t, T) = 0$.

$$S_t = Ke^{-r(T-t)} + I \implies F(t, T) = K = (S_t - I)e^{r(T-t)} \quad (30)$$

Proof.

No Arbitrage. We assume the two scenarios.

1. $F(t, T) < (S_t - I)e^{r(T-t)}$. Then, we buy the forward contract for free at $K = F(t, T)$ and short the stock at S_t . We take the proceeds of the short and invest it at the risk free rate r . At time T , we buy back the stock at $F(t, T)$, and give back the stock to the lender, and additional pay them the dividends they would have received, which is $Ie^{r(T-t)}$. Therefore, our net profit is

$$S_t e^{r(T-t)} - F(t, T) - Ie^{r(T-t)} > 0 \quad (31)$$

2. $F(t, T) > (S_t - I)e^{r(T-t)}$. Then, we buy the stock at S_t and short the forward contract at

$K = F(t, T)$ for free. At time T , we get our income $Ie^{r(T-t)}$, pay back the lender at $S_te^{r(T-t)}$, and execute the contract to sell it at $F(t, T)$. Our net profit is

$$F(t, T) + Ie^{r(T-t)} - S_te^{r(T-t)} > 0 \quad (32)$$

Therefore, we have an arbitrage opportunity in both cases, and therefore it must be the case that $F(t, T) = (S_t - I)e^{r(T-t)}$.

If the stock pays some income at a compounded rate, then we have the following result on the forward price.

Theorem 4.3 ()

If the stock pays a continuous dividend yield q (e.g. $q = 0.02$ means that the stock pays 2% of its value in dividends each year), then the forward price is

$$F(t, T) = S_te^{(r-q)(T-t)} \quad (33)$$

4.5 Valuation of Forward Contracts

Recall from our example of the asset that pays no income. The replication argument gave

$$S_t = V_K(t, T) + Ke^{-r(T-t)} \quad (34)$$

If we substitute $F(t, T) = S_te^{r(T-t)}$ (that is, the forward price is the spot price compounded at the risk free rate), then we get

$$V_K(t, T) = (F(t, T) - K)e^{-r(T-t)} \quad (35)$$

which is the difference between the forward price and the delivery price, discounted back to today.

Theorem 4.4 (Valuation of Forward Contracts)

The value of a forward contract on an asset satisfies

$$V_K(t, T) = (F(t, T) - K)e^{-r(T-t)} \quad (36)$$

Proof.

No Arbitrage. We assume the two scenarios.

4.6 Forward Interest Rates

5 Forward Rates and Libor

One might want to borrow money at a future time, say from T_1 to T_2 , but they are not sure what the interest rate will be. Therefore, they can buy a forward contract that expires at T_1 , with an underlying zero coupon bond that has maturity of T_2 . This essentially allows them to lock in the interest rate r_{T_1, T_2} for a future loan between T_1 and T_2 . This is called the *forward rate*.

Definition 5.1 (Forward Rate)

The **forward rate** at current time t for period T_1 to T_2 ($t \leq T_1 \leq T_2$) is the interest rate (agreed at t) at which one can borrow or lend money from T_1 to T_2 , i.e. the interest rate r_{T_1, T_2} .

Figure 2: Letting r_1 be the interest rate from t to T_1 and r_2 be the interest rate from t to T_2 , we can see that the forward rate $f_{12} = r_{T_1, T_2}$ is the interest rate from T_1 to T_2 .

A simple replication argument gives the following result about the forward rate.

Theorem 5.1 (Forward Rate)

At time t , the fair value of the forward rate f_{12} is given by

$$f_{12} = \frac{(r_2(T_2 - t) - r_1(T_1 - t))}{T_2 - T_1} \quad (37)$$

if the rates are continuously compounded and

$$f_{12} = \left(\frac{(1 + r_2)^{T_2 - t}}{(1 + r_1)^{T_1 - t}} \right)^{\frac{1}{T_2 - T_1}} - 1 \quad (38)$$

Proof.

By the replication argument, consider two portfolios A and B with the same money at time t . A first borrows money at the rate r_1 and then at the forward rate f_{12} , and B borrows at the rate of r_2 . Then, the value of the two portfolios must be the same at time T_2 , and so we have

$$e_{r_1(T_1 - t)} e_{f_{12}(T_2 - T_1)} = e_{r_2(T_2 - t)} \implies f_{12} = \frac{(r_2(T_2 - t) - r_1(T_1 - t))}{T_2 - T_1} \quad (39)$$

and if they are discretely compounded we have

$$(1 + r_1)^{T_1 - t} (1 + f_{12})^{T_2 - T_1} = (1 + r_2)^{T_2 - t} \implies f_{12} = \left(\frac{(1 + r_2)^{T_2 - t}}{(1 + r_1)^{T_1 - t}} \right)^{\frac{1}{T_2 - T_1}} - 1 \quad (40)$$

Theorem 5.2 (Forward Price of Zero Coupon Bonds)

For $T_1 \leq T_2$, consider a forward contract with maturity T_1 on a ZCB with maturity T_2 . That is, the underlying asset price is $S_t = Z(t, T_2)$. Then, the forward price, i.e. the price where one can (for no cost) agree to buy a forward contract on the T_2 -ZCB with an expiry date of T_1 , is

$$F(t, T_1, T_2) = \frac{Z(t, T_2)}{Z(t, T_1)} \quad (41)$$

Proof.

Let

1. Portfolio A be one ZCB maturing at T_2 .
2. Portfolio B be one long forward with delivery price K , and K ZCBs maturing at T_1 .

Corollary 5.1 ()

Since the value of a ZCB with annually compounded rate is

$$Z(t, T_i) = \frac{1}{(1 + r_i)^{T_i - t}} \text{ for } i = 1, 2 \quad (42)$$

we can substitute to see that the forward price of a ZCB is

$$F(t, T_1, T_2) = \frac{Z(t, T_2)}{Z(t, T_1)} = \frac{(1 + r_1)^{T_1 - t}}{(1 + r_2)^{T_2 - t}} = \frac{1}{(1 + f_{12})^{T_2 - T_1}} \quad (43)$$

6 Swaps

7 Futures

Note that when trading futures, it is exchange traded so every trade between a buyer and a seller must go through a clearing house. Let's talk about the properties of a future contract.

Definition 7.1 (Components of a Future Contract)

A future contract must specify the following components.

1. **Asset:** What is the underlying asset?
2. **Grade:** If the asset is a commodity, we want to specify the quality of the asset allowed at some price. Alternatively, we can talk about the **expected grade**, which allows for a range of grades depending on the actual grade of the contract.
3. **Contract Size:** The quantity of the asset. How much of it is being traded? The price of the contract shown is usually for one unit of the underlying commodity, so the actual value of the contract is the price times the contract size. These sizes are determined by the exchange (should be large enough for institutions to be interested in but not too big to be unaffordable). Furthermore, the mini contracts are less liquid and have a higher bid ask spread.
4. **Delivery Location:** Where is the location? This is also standardized by the exchange, and the buyer must personally deliver the asset from these locations to wherever the asset is needed.
5. **Delivery Time:** The month of contract, which is the month that the commodity will be delivered and is not necessarily the same as the expiration date.
6. **Price Increments:** The minimum price change allowed.
7. **Daily Price Limits:** The maximum price change allowed in a day, and any price change beyond this limit will halt trading (called *limit up* or *limit down*). However, trading can still resume if it goes down.
8. **Position Limits:** The maximum number of contracts that a trader can hold. This is to prevent parties from cornering a market.

Example 7.1 (Futures Pricing and Size Standards)

Here is an overview of the pricing and size standards of many futures contracts set by the exchange.

Underlying	Size	Increments	Ex. Quote
Crude Oil (CL)	1000 barrels	1 c (\$10.00)	\$86.73
Crude Oil (CL) Mini	500 barrels	1 c (\$5.00)	\$86.73
Natural Gas (NG)	10,000 mmBtu	$\frac{1}{10}$ c (\$10.00)	\$2.843
Corn (ZC)	5000 Bushels	$\frac{1}{8}$ c (\$12.50)	$400\frac{3}{8}$ c
Wheat (ZW)	5000 Bushels	$\frac{1}{8}$ c (\$12.50)	$568\frac{1}{4}$ c
Soybean (ZS)	5000 Bushels	$\frac{1}{8}$ c (\$12.50)	$1655\frac{1}{2}$ c
Gold (CS)	100 Troy Ounces	10 c (\$10.00)	\$2349.10
Silver (SI) Full	5000 Troy Ounces	$\frac{1}{10}$ c (\$5.00)	\$27.247
Silver (SI) Micro	1000 Troy Ounces	$\frac{1}{10}$ c (\$1.00)	
Copper (NG)	25,000 Pounds	$\frac{1}{200}$ c (\$12.50)	
E-Mini S&P 500	50	0.25 c (\$12.50)	
E-Mini Nasdaq 100	20	0.25 c (\$5.00)	
E-Mini Dow	5	1 c (\$5.00)	
E-Mini Russell 2000	50	0.10 c (\$5.00)	
Micro E-Mini S&P 500	5	0.25 c (\$1.25)	
Micro E-Mini Nasdaq 100	2	0.25 c (\$0.50)	
Micro E-Mini Dow	0.5	1 c (\$0.50)	
Micro E-Mini Russell 2000	5	0.10 c (\$0.50)	
Treasury Bonds	\$100,000	$\frac{1}{32}$ c (\$31.25)	
Treasury Bonds	\$200,000	$\frac{1}{32}$ c (\$62.50)	

Table 1: Standards of Futures Contracts

1. **Corn** is delivered to Toledo, Ohio.
2. **Oil** (WTI) is delivered to Cushing, Oklahoma.
1. For oil, natural gas, and copper, the delivery month is the month after the expiration month and delivers on all months.
2. For corn, wheat, and soybean, we only deliver on the months of March, May, July, September, and December.

Example 7.2 (Harvest and Delivery Standards)

While most futures deliver throughout the year, for grain (corn, wheat, soybean) futures, they deliver on the months of March, May, July, September, and December. This is because these are the months of the harvest.

It turns out that this discrepancy is important in analyzing the convergence of the future price to the spot price and determining the risk.

8 Options

Definition 8.1 (Long Options)

An option is a contract that gives the owner the right, but not the obligation, to buy or sell a specific asset (the **underlying**) at a specific price K (**strike** or **exercise price**) at a specific date T (**expiration date**). When you buy (long)

1. a **call option** for $\$X$, then you have the *right* to buy the asset and the seller has the *obligation* to sell.

Figure 3: Note that the buyer has limited loss and has unlimited gain with the long put, while the seller has limited gain and unlimited loss with the short put.

2. a **put option** for $\$X$, then you have the *right* to sell the asset and the seller has the *obligation* to buy.

Figure 4: Note that the buyer has limited loss and limited gain, and the seller also has limited loss and limited gain.

There are three types of options.

1. **American style** options can be exercised anytime during the life of the option.
2. **European style** options can only be exercised at the expiration date.
3. **Bermuda style** options can be exercised at specific dates during the life of the option.

This has nothing to do with which continent the options are trading in. It is just a name. Most exchange traded options are American style and most OTC options are European style.

Note that unlike forwards or futures, the premium changes hands, i.e. the buyer pays the seller to enter the contract.

9 Exercises

Exercise 9.1 (Hull 1.3)

What is the difference between entering in to a long forward contract when the forward price is $\$50$ and taking a long position in a call option with a strike price of $\$50$?

Solution 9.1

The answer is clear when we look at the payoff graph for each one.

1. The first difference is that the forward contract renders both parties obligated to buy or sell the underlying at a future time, while the option only gives the seller the obligation to sell, if the buyer requests it.
2. The second is that money is paid to enter into the options contract by the buyer, while the forward contract does not.
3. Both profits/losses are unlimited in the forward contract, while in the options contract, the buyer has limited loss and the seller has unlimited loss.
4. By having the safety of a limited downside for the call options buyer, they get a slightly lower payoff $S_T - C_0$ compared to the forward contract, which is S_T . Therefore, the options buyer doesn't actually make a profit until the price of the underlying asset is at least $C_0 + K$.
5. If $S_T > K$, we would wish we were taking the forward, and if $S_T < K$, then we wish we were taking the call option.

Figure 5: The payoff graph for the forward contract and the call option from the buyers side.

Definition 9.1 (Pips)

For the next problem, it helps to know that a **pip** is 1/100 of a cent.

Exercise 9.2 (Hull 1.5)

An investor enters into a short forward contract to sell 100,000 British Pounds for US dollars at an exchange rate of 1.5 dollars per pound. How much does the investor gain or lose if the exchange rate at the expiration date is 1.4900 dollars per pound? What if it is 1.5200 dollars per pound?

Solution 9.2

Note that we must specify the currency of the profit or loss. It turns out that the payoff will always be in the currency that the investor is selling. The investor is selling the forward, so they are obligated to sell it at 1.5000 dollars per pound.

1. If the rate is 1.4900, then the investor sells the pounds for 150,000 USD and can buy a little bit more than 100,000 pounds. In fact, they are making a profit of $100,000 \cdot 0.0100 = 1,000$ dollars.

2. If the rate is 1.52, then the investors sells the pounds for 150,000 USD and can buy a little less than 100,000 pounds, so they lose $100,000 \cdot 0.0200 = 2,000$ dollars.

Exercise 9.3 (Hull 1.6)

A trader enters into a short cotton futures contract when the futures price is 50 cents per pound. The contract is for the delivery of 50,000 pounds. At the end of the contract, the price of cotton is 48.20 or 51.30 per pound. What is the trader's gain or loss?

Solution 9.3

The trader is selling the cotton, and the buyer is obligated to buy. Therefore,

1. the trader makes $(50 - 48.20) \cdot 50,000 = 1.8 \cdot 50,000 = 90,000$ cents, or \$900 if the price is 48.20.
2. the trader loses $(51.30 - 50) \cdot 50,000 = 1.3 \cdot 50,000 = 65,000$ cents, or \$650 if the price is 51.30.

Exercise 9.4 (Hull 1.16)

A trader writes (sells) a December put option with a strike price of \$30. The price of the option is \$4. Under what circumstances does the trader make a profit?

Solution 9.4

Even without a payoff graph, we can see that since I'm selling the option, I'm getting \$4. Now, I'm obligated to buy the asset (since it's a put) at \$30, and therefore I will profit if the price of the asset is above \$30. However, since I already have the cushion of \$4, I'm really profiting if the asset price $S_T > 26$.

Figure 6: The payoff graph for the put option from the sellers side.

Exercise 9.5 (Hull 1.22)

I am in a long forward contract and a long put option at the same strike price K . What is the payoff of this position at expiration?

Solution 9.5

You can simply draw the profit-loss diagram.

Figure 7: The payoff graph for the long forward and long put option at the same strike price.

Exercise 9.6 (Hull 1.23)

We have a **Index Currency Option Note (ICON)** which states the following:

1. If the exchange rate $USD.JPY < 169$, then the bond pays 1000 USD.
2. If $84.50 \leq USD.JPY \leq 169$, then the bond pays

$$1000 - \max \left\{ 0, 1000 \left(\frac{169}{S_T} - 1 \right) \right\} \quad (44)$$

3. If $USD.JPY < 84.50$, then the bond pays nothing.

Show that this ICON is a combination of a bond and two options.

Solution 9.6

This seems a bit easy since we can draw the payoff diagram as such.

Figure 8

However, the underlying asset is shown in yen and the payoff in USD, which complicates calculations. You should rather change the underlying to be USD by changing $USD.JPY$ to $JPY.USD$. Then, we can do some quick sketches to find that you should have a

1. Bond at \$1000.
2. Short call at $1/169$ for \$1000.
3. Long call at $1/84.50$ for \$1000.

Figure 9

10 Appendix

Futures are mostly cash settled (e.g. look at futures on SP500 index. you can't deliver fractional shares.)

Margin calls with futures.

The difference between the spot and the futures price is called the basis gap/risk. They tend to converge as we approach the expiration date.

Order types (market, limit - default, stop), which exists for both long and short futures.

Regulations are done by the CFTC (Dodd-Frank Act expands CFTC oversight to OTC markets due to 2008). Accounting (does unrealized gains count as taxable income?) and taxes can be country specific.

Talk about derivatives in general - stuff like payoff graphs - definitions of derivatives

Forwards & Futures - how they work, with trading, delivery, quality of goods, settlement (delivery or cash settled). Does delivery actually happen? You must actually request to have it delivered to a warehouse you set up. This could have inventory/delivery fees as well. - basis risk (spot price of asset A is S_A , and the futures is F_A). (8) - hedging strategies with futures (short & long futures) hedge ratio, with cross-hedging, and minimizing the variance of our position. (is this delta-hedging?) - stock index futures (you need CAPM to evaluate this)
