A lot of this is based off of [Hof09]. We have seen that Bayesian statistics depends on having some initial belief about an event. Upon some observation, we can gain some sort of information about the event, allowing us to *modify* our prior distribution to a new one, called the posterior distribution. This simple property is the reason why Bayesian statistics is so useful for machine learning. The way we do this is through **Bayes' Rule**, which states

$$p(H | D) = \frac{p(D | H) p(H)}{p(D)} \quad (1)$$

Note that:

1. H is the **hypothesis** whose probability may be affected by **data** D , also called **evidence**.
2. $p(H)$ is the **prior distribution**, our initial hypothesis of what the distribution would have been.
3. $p(H | D)$ is the **posterior distribution**, which was determined upon observing the event B .
4. $p(D | H)$ is the **likelihood**. If you were to assume that A is true, then the likelihood tells you the probability of getting result B .
5. $p(D)$ is the **marginal likelihood**, which is calculated by conditioning on A

$$p(D) = \sum_H p(D | H) p(H) \text{ or } p(D) \int_H p(D | H) p(H) dH \quad (2)$$

When computing our prior, the outcomes H are the **hypotheses**. We can assume that hypotheses are mutually exclusive and exhaustive (if one of these is true, it can't be some undefined third option). These assumptions are reasonable since it is almost always possible to redefine an arbitrary set of hypotheses into a set of hypotheses that *are* mutually exclusive and exhaustive.

There are multiple ways to write Bayes rule. When attempting to calculate the posterior, we can see that $p(D)$ is really just a normalization constant and therefore does not affect the type of distribution the posterior is. So, we can in effect write the above as

$$p(H | D) \propto p(D | H) p(H) \quad (3)$$

or

$$\text{Posterior} \propto \text{Prior} \times \text{Likelihood} \quad (4)$$

where the \propto symbol means “proportional to.” We use this notation more often when calculating posteriors since the normalizing constant isn't as important as finding the shape of the posterior density.

1 Single Parameter Families

1.1 Exponential Family

1.2 Conjugate Priors

1.3 Computing Posteriors with Beta Prior and Binomial Likelihood

The motivation behind the Beta distribution is that it satisfies **conjugacy** with a binomial likelihood. That is, assume that we have some data \mathbf{x} of N observations containing m successes and $N - m$ failures (note that this observation \mathbf{x} was in a way "reduced" to the information of only the number of successes m). We assume that there is some true success rate θ (between 0 and 1, of course) coming from these samples, and our job is to try and guess the true rate to the best of our abilities.

Before we even observe the data \mathbf{x} , our initial guess of θ might be modeled by the prior distribution $\theta \sim \text{Beta}(a, b)$. Furthermore, the likelihood is clearly a binomial (since it represents the probability of getting m successes out of N samples with fixed rate of success θ), so $m | \theta \sim \text{Binomial}(N, \theta)$. With these conditions, we claim that the posterior is also a beta, since

$$\begin{aligned} p(\theta | m) &\propto p_\theta(\theta) p(m | \theta) \\ &\propto \theta^{a-1} (1 - \theta)^{b-1} \cdot \theta^m (1 - \theta)^{N-m} \\ &= \theta^{a+m-1} (1 - \theta)^{b+N-m-1} \end{aligned}$$

1.4 Bayesian Inference for Gaussian

The maximum likelihood framework gave point estimates for the parameters μ and Σ . Now we develop a Bayesian treatment by introducing prior distributions over these parameters. Given a set of N D -dimensional observations $\mathbf{X} = \{x_1, \dots, x_n\}$, the likelihood function is given by (the unnormalized function of μ):

$$p(\mathbf{X} | \mu, \Sigma) = \prod_{n=1}^N p(x_n | \mu, \Sigma) = \frac{1}{(2\pi)^{D/2}} \frac{1}{|\Sigma|^{1/2}} \exp \sum_{n=1}^N \left(-\frac{1}{2} (x_n - \mu)^T \Sigma^{-1} (x_n - \mu) \right) \quad (5)$$

The likelihood function takes the form of the exponential of a quadratic form in μ . Thus, if we choose a prior $p(\mu)$ given by a Gaussian, it will be a conjugate distribution for this likelihood function. Taking our prior distribution to be

$$p(\mu, \Sigma) = \mathcal{N}(\mu, \Sigma | \mu_0, \Sigma_0) \quad (6)$$

The similarity of the symbols μ, Σ with μ_0, Σ_0 may be slightly confusing. We can think as such: μ, Σ are random variables that determine the parameters of some Gaussian distribution. But the values μ, Σ are uncertain, and their possible values with probabilities take the form of another distribution $\mathcal{N}(\mu_0, \Sigma_0)$. The posterior distribution is given by the familiar formula

$$p(\mu, \Sigma | \mathbf{X}) \propto p(\mathbf{X} | \mu, \Sigma) p(\mu, \Sigma) \quad (7)$$

which is another Gaussian $p(\mu | \mathbf{X}) = \mathcal{N}(\mu, \Sigma | \mu_N, \Sigma_N)$. Let us place a few conditions for simplification. Since every Gaussian density can be represented as a product of independent univariate Gaussians, we can work with univariate Gaussians. Furthermore, let us assume that the true value of σ is known, so all we have to do is find the posterior distribution of μ using the prior density $\mathcal{N}(\mu | \mu_0, \sigma_0^2)$. We have our prior and likelihood to be the following. Note that while the likelihood distribution is pretty much given, we have the flexibility to choose what our prior distribution is. We have only set the prior as a Gaussian simply because it is a conjugate form and therefore will greatly simplify calculations.

$$p(\mu) = \mathcal{N}(\mu | \mu_0, \sigma_0^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{1}{2\sigma^2}(\mu - \mu_0)^2\right)$$

$$p(\mathbf{X} | \mu) = \prod_{n=1}^N p(x_n | \mu) = \frac{1}{(2\pi\sigma^2)^{N/2}} \exp\left(-\frac{1}{2\sigma^2} \sum_{n=1}^N (x_n - \mu)^2\right)$$

which gives a posterior $p(\mu | \mathbf{X}) = \mathcal{N}(\mu | \mu_N, \sigma_N^2)$ where

$$\mu_N = \frac{\sigma^2}{N\sigma_0^2 + \sigma^2} \mu_0 + \frac{N\sigma_0^2}{N\sigma_0^2 + \sigma^2} \mu_{ML}$$

$$\frac{1}{\sigma_N^2} = \frac{1}{\sigma_0^2} + \frac{N}{\sigma^2}$$

and μ_{ML} is the maximum likelihood solution for μ given by the sample mean $\mu_{ML} = \frac{1}{N} \sum_{n=1}^N x_n$. These values make sense. We can see that the mean of the posterior distribution μ_N is a compromise between the prior mean μ_0 and maximum likelihood solution μ_{ML} . If the number of observed data points $N = 0$, then it is simply the prior mean, but for $N \rightarrow \infty$, the posterior mean is given by the maximum likelihood solution since the data “overpowers” the prior mean assumption.

Now, suppose that the mean of the Gaussian over the data is known and we wish to infer the variance. For convenience, let us work with the precision $\lambda = \frac{1}{\sigma^2}$ over the variance. The likelihood function for λ is

$$p(\mathbf{X} | \lambda) = \prod_{n=1}^N \mathcal{N}(x_n | \mu, \lambda^{-1}) \propto \lambda^{N/2} \exp\left(-\frac{\lambda}{2} \sum_{n=1}^N (x_n - \mu)^2\right) \quad (8)$$

Note that since this is a function of λ , it behaves differently than the likelihood function of μ , even though they are of the same form. Since the likelihood function is proportional to the product of a power of λ and the exponential of a linear function of λ , we must find a prior distribution $p(\lambda)$ with precisely these proportional properties identical to that of the likelihood. Fortunately, the Gamma distribution satisfies them, defined by

$$p(\lambda | a_0, b_0) = \text{Gamma}(\lambda | a_0, b_0) = \frac{1}{\Gamma(a_0)} b_0^{a_0} \lambda^{a_0-1} \exp(-b_0 \lambda) \quad (9)$$

Using Bayes rule and multiplying gives the posterior density

$$p(\lambda | \mathbf{X}) \propto \lambda^{a_0-1} \lambda^{N/2} \exp\left(-b_0 \lambda - \frac{\lambda}{2} \sum_{n=1}^N (x_n - \mu)^2\right) \quad (10)$$

which is indeed the density of a $\text{Gamma}(\lambda | a_N, b_N)$ distribution, where

$$a_N = a_0 + \frac{N}{2}$$

$$b_N = b_0 + \frac{1}{2} \sum_{n=1}^N (x_n - \mu)^2 = b_0 + \frac{N}{2} \sigma_{ML}^2$$

where σ_{ML}^2 is the maximum likelihood estimator of the variance. Now, suppose that both the mean and precision are unknown. To find a conjugate prior, we consider the dependence of the likelihood function on μ and λ .

$$p(\mathbf{X} | \mu, \lambda) = \prod_{n=1}^N \left(\frac{\lambda}{2\pi}\right)^{1/2} \exp\left(-\frac{\lambda}{2}(x_n - \mu)^2\right)$$

$$\propto \left(\lambda^{1/2} \exp\left(-\frac{\lambda \mu^2}{2}\right)\right)^N \exp\left(\lambda \mu \sum_{n=1}^N x_n - \frac{\lambda}{2} \sum_{n=1}^N x_n^2\right)$$

We now wish to identify a prior distribution $p(\mu, \lambda)$ that has the same functional dependence on μ and λ as the likelihood function and that should therefore take the form

$$\begin{aligned} p(\mu, \lambda) &\propto \left(\lambda^{1/2} \exp \left(-\frac{\lambda \mu^2}{2} \right) \right)^\beta \exp(c\lambda\mu - d\lambda) \\ &= \exp \left(-\frac{\beta\lambda}{2} \left(\mu - \frac{c}{\beta} \right)^2 \right) \lambda^{\beta/2} \exp \left(-\left(d - \frac{c^2}{2\beta} \right) \lambda \right) \end{aligned}$$

where c, d, β are constants. Since we can always write $p(\mu, \lambda) = p(\mu | \lambda)p(\lambda)$, we can find $p(\mu | \lambda)$ and $p(\lambda)$ by inspection. We have just shown that $p(\mu | \lambda)$ is a Gaussian whose precision is a linear function of λ and that $p(\lambda)$ is a gamma distribution, so the normalized prior takes the form

$$p(\mu, \lambda) = \mathcal{N}(\mu | \mu_0, (\beta\lambda)^{-1}) \text{Gamma}(\lambda | a, b) \quad (11)$$

which is called the **Gaussian-Gamma distribution**. Note that this is not simply the product of an independent Gaussian prior over μ and a gamma prior over λ , because the precision of μ is a linear function of λ . The extension of this to multivariate random variables is straightforward.

1.5 Inference over Periodic Distributions

Although Gaussian distributions are of great significance, there are situations in which they are inappropriate as density models for continuous variables (e.g. wind direction or quantities periodic over 24 hours). Such quantities are conveniently represented using an angular (polar) coordinate $0 \leq \theta < 2\pi$. Let us consider the problem of evaluating the mean of a set of observations $\theta = \{\theta_1, \theta_2, \dots, \theta_N\}$ of a periodic variable measured in radians. The simple average $(\theta_1 + \dots + \theta_N)/N$ is strongly coordinate dependent. To find an invariant measure of the mean, we can see that the observations can be viewed as points on the unit circle and can therefore be described instead by two-dimensional unit vectors x_1, \dots, x_N , where $x_n = (\cos \theta_n, \sin \theta_n)$. We can average these vectors and compute its angle to find this average angle.

$$\bar{x} = \frac{1}{N} \sum_{n=1}^N x_n = \left(\frac{1}{N} \sum_{n=1}^N \cos \theta_n, \frac{1}{N} \sum_{n=1}^N \sin \theta_n \right) \implies \bar{\theta} = \tan^{-1} \left(\frac{\sum_{n=1}^N \sin \theta_n}{\sum_{n=1}^N \cos \theta_n} \right) \quad (12)$$

In general, any distribution $p(\theta)$ that have period 2π must be defined such that it is nonnegative, integrate to 1, and be periodic.

$$\begin{aligned} p(\theta) &\geq 0 \\ \int_0^{2\pi} p(\theta) d\theta &= 1 \\ p(\theta + 2\pi) &= p(\theta) \end{aligned}$$

We can obtain a Gaussian-like distribution that satisfies these three properties. Consider a 2-dimensional Gaussian over variables x_1, x_2 having mean $\mu = (\mu_1, \mu_2)$ and a covariance matrix $\Sigma = \sigma^2 I$. This gives us

$$p(x_1, x_2) = \frac{1}{2\pi\sigma^2} \exp \left(-\frac{(x_1 - \mu_1)^2 + (x_2 - \mu_2)^2}{2\sigma^2} \right) \quad (13)$$

Now, suppose that we consider the value of this distribution along a circle of fixed radius. Then, this distribution will be periodic, although it will not be normalized. We can determine the form of this distribution by transforming from Cartesian coordinates to polar coordinates (r, θ) (so that $x_1 = r \cos \theta$, $x_2 = r \sin \theta$) and keeping r constant.

Figure 1: Circular normal change of basis

This transformation from $\mathbb{R}^2 \rightarrow [0, 2\pi)$ defined

$$(x_1, x_2) \mapsto \tan^{-1} \frac{y}{x} \quad (14)$$

simply takes the "circular" cross section of the Gaussian and maps those values.

Figure 2: Circular cross section visualization

The value of r is not important so we assume $r = 1$. With some algebra and trig identities, we have the **circular normal**, or **von Mises distribution**, of form

$$p(\theta | \theta_0, m) = \frac{1}{2\pi I_0(m)} \exp(m \cos(\theta - \theta_0)) \quad (15)$$

where the parameter θ_0 corresponds to the mean of the distribution while m is analogous to the precision for the Gaussian. The normalization coefficient $I_0(m)$ is the zeroth-order Bessel function of the first kind, defined by

$$I_0(m) = \frac{1}{2\pi} \int_0^{2\pi} \exp(m \cos \theta) d\theta \quad (16)$$

For large m , the distribution becomes approximately Gaussian. Considering the maximum likelihood esti-

mators for the parameters θ_0 and m for the circular normal, the log likelihood function is given by

$$\ln p(\theta | \theta_0, m) = -N \ln(2\pi) - N \ln(I_0(m)) + m \sum_{n=1}^N \cos(\theta_n - \theta_0) \quad (17)$$

The maximum estimator for the mean is

$$\theta_0^{ML} = \tan^{-1} \left(\frac{\sum_n \sin \theta_n}{\sum_n \cos \theta_n} \right) \quad (18)$$

while that of m can be evaluated numerically.

1.6 Exponential Family of Distributions

The probability distributions so far are contained within the **exponential family** of distributions, which have important properties in common. The exponential family of distributions over $x \in \Omega \subset \mathbb{R}^D$, given parameters η , is defined to be the set of distributions of the form

$$p(x | \eta) = h(x)g(\eta) \exp(\eta^T u(x)) \quad (19)$$

where x may be a scalar or vector, discrete or continuous. Here, η are called the **natural parameters** of the distribution, and $u(x)$ is some function of x . The function $g(\eta)$ can be interpreted as the normalizing coefficient and therefore satisfies

$$g(\eta) \int_{x \in \Omega} h(x) \exp(\eta^T u(x)) dx = 1 \quad (20)$$

with the integration replaced by a summation if x is discrete.

Now, consider a set of iid data denoted by $\mathbf{X} = \{x_1, \dots, x_n\}$, for which the likelihood function is given by

$$p(\mathbf{X} | \eta) = \left(\prod_{n=1}^N h(x_n) \right) g(\eta)^N \exp \left(\eta^T \sum_{n=1}^N u(x_n) \right) \quad (21)$$

Setting the gradient of $\ln p(\mathbf{X} | \eta)$ with respect to η to 0, we can the following condition to be satisfied by the maximum likelihood estimator η_{ML} :

$$-\nabla \ln g(\eta_{ML}) = \frac{1}{N} \sum_{n=1}^N u(x_n) \quad (22)$$

which can in principle be solved to obtain η_{ML} . The solution for the maximum likelihood estimator depends on the data only through $\sum_n u(x_n)$, which is therefore called the sufficient statistic of this distribution. Therefore, we do not need to store the entire data set itself but its sufficient statistic.

In general, for a given probability distribution $p(\mathbf{X} | \eta)$, we can seek a prior that is conjugate to the likelihood function, so that the posterior distribution has the same functional form as the prior. Given that the likelihood function is in the exponential family, there exists a conjugate prior that can be written in the form

$$p(\eta) = p(\eta | \chi, \nu) = f(\chi, \nu) g(\eta)^\nu \exp(\nu \eta^T \chi) \quad (23)$$

where $f(\chi, \nu)$ is a normalization coefficient, and $g(\eta)$ is the same function as the one appearing in the exponential family form of likelihood function. Indeed, multiplying this conjugate with the exponential family likelihood gives

$$p(\eta | \mathbf{X}, \chi, \nu) \propto g(\eta)^{\nu+N} \exp \left(\eta^T \left(\sum_{n=1}^N u(x_n) + \nu \chi \right) \right) \quad (24)$$

2 Bias Variance Decomposition

Determination of the predictive distribution $p(y|x)$ given data \mathcal{D} is the goal of statistical inference, as we have seen. That is, posterior $p(y|x, \mathcal{D})$ tells us the distribution of y if we have a new data point x . But after this inference step, we must look now at the **decision step**: we must determine a function $h(x)$ that deterministically predicts a value y , without predictions. That is, we must have some algorithm to make a decision.

Let us zoom out for a better overview. Let \mathcal{D} be our training data of N points. We can assume that each point $(x_i, y_i) \in \mathcal{D}$ was *generated* independently by a joint distribution $p(x, y)$. If we were to get another data point, we would just generate one from the density $p(x, y)$. Usually, we have fixed input data x and knew that the output y given x would be $p(y|x)$. But if we loosen our constraint on x , we would get

$$p(x, y) = p(y|x)p(x) \quad (25)$$

which states that each data point in \mathcal{D} is gotten by generating a value of x with probability $p(x)$, and then generating a y given this x . Let us also denote \mathcal{A} as our machine learning algorithm, which we can interpret as a function that takes in data \mathcal{D} and outputs the hypothesis function $h_{\mathcal{D}}$.

$$\mathcal{A}(\mathcal{D}) = h_{\mathcal{D}} \quad (26)$$

Then, given that the next new data point (x, y) is generated, we can set our **test error**, or **loss/cost function**, of $h_{\mathcal{D}}$ to be

$$L(h_{\mathcal{D}}, (x, y)) = [h_{\mathcal{D}}(x) - y]^2 \quad (27)$$

This loss function basically calculates the inaccuracy of whatever hypothesis function $h_{\mathcal{D}}$ we have on the data (x, y) , which in this case is the square of the residual. There can be other types of loss functions, but we will consider the squares loss function for now. Given $h_{\mathcal{D}}$, we can also calculate the expected test error by conditioning over all x, y drawn from P .

$$\text{Expected Test Error given } h_{\mathcal{D}} \implies \mathbb{E}_{x, y \sim P} [(h_{\mathcal{D}}(x) - y)^2] = \int_x \int_y (h_{\mathcal{D}}(x) - y)^2 p(x, y) dy dx \quad (28)$$

However, note that we can treat the N data points \mathcal{D} also as a random variable coming from the joint distribution of N P 's. Therefore, we can take each possible dataset \mathcal{D} , calculate $h_{\mathcal{D}} = \mathcal{A}(\mathcal{D})$ with our algorithm, and average them out to get the expected hypothesis function \bar{h} . We can interpret \bar{h} as the "ideal regressor" that we are trying to build, but with limited data \mathcal{D} , we can only build $h_{\mathcal{D}}$ that deviates from \bar{h} .

$$\bar{h} = \mathbb{E}_{\mathcal{D} \sim P^N} [\mathcal{A}(\mathcal{D})] = \int_{\mathcal{D}} h_{\mathcal{D}} P(\mathcal{D}) d\mathcal{D} \quad (29)$$

So, we can compute the expected error of the *entire algorithm* \mathcal{A} by marginalizing over all x, y given $h_{\mathcal{D}}$ and marginalizing over all \mathcal{D} . Remember that $\mathcal{D} \sim P^N$ is our training data of N points, and $(x, y) \sim P$ is our $(n+1)$ th data point. Therefore, the expected test error of our *algorithm* for the $(n+1)$ th data point is

$$\mathbb{E}_{(x, y) \sim P, \mathcal{D} \sim P^N} ([h_{\mathcal{D}}(x) - y]^2) = \int_{\mathcal{D}} \int_x \int_y [h_{\mathcal{D}}(x) - y]^2 p(x, y) p(\mathcal{D}) dy dx d\mathcal{D} \quad (30)$$

The integral above looks quite intimidating, so let us decompose it. We just have to use a trick where we subtract and add the same term $\bar{h}(x)$.

$$\begin{aligned} \mathbb{E}_{(x, y), \mathcal{D}} ([h_{\mathcal{D}}(x) - y]^2) &= \mathbb{E}_{(x, y), \mathcal{D}} ([(h_{\mathcal{D}}(x) - \bar{h}(x)) + (\bar{h}(x) - y)]^2) \\ &= \mathbb{E}_{(x, y), \mathcal{D}} ([h_{\mathcal{D}}(x) - \bar{h}(x)]^2) + \mathbb{E}_{(x, y), \mathcal{D}} ([\bar{h}(x) - y]^2) \\ &\quad + 2\mathbb{E}_{(x, y), \mathcal{D}} ([h_{\mathcal{D}}(x) - \bar{h}(x)] [\bar{h}(x) - y]) \end{aligned}$$

But I claim that the last term vanishes. It is easy to see why because

$$\begin{aligned}
\mathbb{E}_{(x,y),\mathcal{D}} [(h_{\mathcal{D}}(x) - \bar{h}(x)) (\bar{h}(x) - y)] &= \mathbb{E}_{(x,y)} [E_{\mathcal{D}} [h_{\mathcal{D}}(x) - \bar{h}(x)] (\bar{h}(x) - y)] \\
&= \mathbb{E}_{(x,y)} [(E_{\mathcal{D}} [h_{\mathcal{D}}(x)] - \bar{h}(x)) (\bar{h}(x) - y)] \\
&= \mathbb{E}_{(x,y)} [(\bar{h}(x) - \bar{h}(x)) (\bar{h}(x) - y)] \\
&= \mathbb{E}_{(x,y)} [0] \\
&= 0
\end{aligned}$$

Therefore, we can see that the expected value of the error of an algorithm consists of two terms: the variance and the second term.

$$\mathbb{E}_{(x,y),\mathcal{D}} ([h_{\mathcal{D}}(x) - y]^2) = \mathbb{E}_{(x,y),\mathcal{D}} ([h_{\mathcal{D}}(x) - \bar{h}(x)]^2) + \mathbb{E}_{(x,y),\mathcal{D}} ([\bar{h}(x) - y]^2) \quad (31)$$

The second term is the expected value of the average prediction minus the y -value of the new point. Now, we do the same trick: Let the expected value of y given x be $\bar{y}(x) = \mathbb{E}_{y|x}(y) = \int y p(y|x) dx$. This function $\bar{y}(x)$ is the ideal regressor predicting y from x . Then, we have

$$\begin{aligned}
\mathbb{E}_{x,y} [(\bar{h}(x) - y)^2] &= \mathbb{E}_{x,y} [(\bar{h}(x) - \bar{y}(x)) + (\bar{y}(x) - y)^2] \\
&= \underbrace{\mathbb{E}_{x,y} [(\bar{y}(x) - y)^2]}_{\text{Noise}} + \underbrace{\mathbb{E}_x [(\bar{h}(x) - \bar{y}(x))^2]}_{\text{Bias}^2} + 2 \mathbb{E}_{x,y} [(\bar{h}(x) - \bar{y}(x)) (\bar{y}(x) - y)]
\end{aligned}$$

where the third term vanishes since

$$\begin{aligned}
\mathbb{E}_{x,y} [(\bar{h}(x) - \bar{y}(x)) (\bar{y}(x) - y)] &= \mathbb{E}_x [\mathbb{E}_{y|x} [\bar{y}(x) - y] (\bar{h}(x) - \bar{y}(x))] \\
&= \mathbb{E}_x [(\bar{y}(x) - \mathbb{E}_{y|x} [y]) (\bar{h}(x) - \bar{y}(x))] \\
&= \mathbb{E}_x [(\bar{y}(x) - \bar{y}(x)) (\bar{h}(x) - \bar{y}(x))] \\
&= \mathbb{E}_x [0] \\
&= 0
\end{aligned}$$

Therefore, the expected test error is precisely the sum of three things.

$$\mathbb{E}_{x,y,\mathcal{D}} [(h_{\mathcal{D}}(x) - y)^2] = \underbrace{\mathbb{E}_{x,\mathcal{D}} [(h_{\mathcal{D}}(x) - \bar{h}(x))^2]}_{\text{Variance}} + \underbrace{\mathbb{E}_{x,y} [(\bar{y}(x) - y)^2]}_{\text{Noise}} + \underbrace{\mathbb{E}_x [(\bar{h}(x) - \bar{y}(x))^2]}_{\text{Bias}^2}$$

To understand this term a bit deeper, recall the following: The function $\bar{y}(x)$, which outputs the expected value of y given x , is the best possible regressor we can have. There are many different algorithms that we can choose to approximate $\bar{y}(x)$, so let us choose one learning algorithm \mathcal{A} . We just feed an arbitrary dataset \mathcal{D} to \mathcal{A} , which outputs a hypothesis function $h_{\mathcal{D}}$. But this hypothesis function $h_{\mathcal{D}}$ is really just an approximation of the *ideal* hypothesis function \bar{h} , which is the expectation of all hypotheses $h_{\mathcal{D}}$ (i.e. the hypothesis that \mathcal{A} should generate when we feed it an infinite amount of data). So, by feeding \mathcal{D} to \mathcal{A} , it generates a hypothesis function $h_{\mathcal{D}}(x)$, which approximates $\bar{h}(x)$, which hopefully is a good estimate of $\bar{y}(x)$.

1. The difference between a generated hypothesis function $h_{\mathcal{D}}(x)$ and the ideal hypothesis that it is trying to estimate according to learning algorithm \mathcal{A} is represented by the variance. The variance term tells us how far each generated hypothesis $h_{\mathcal{D}}$ deviates from the ideal \bar{h} .
2. The difference between the ideal hypothesis $\bar{h}(x)$ (according to algorithm \mathcal{A}) and the ideal regressor *in general* $\bar{y}(x)$ is captured in the bias term. The bias term tells us how far our algorithm's ideal hypothesis deviates from the expectation of the conditional $p(y|x)$.

3. The noise term represents the difference between the true value of y and the best possible regressor $\bar{y}(x)$. But since the best we can do is find the expectation of the conditional $p(y|x)$, the deviation of the true values y from the mean \bar{y} is simply the noise. For example, if we have $p(y|x) = \mathcal{N}(y|w^T\phi(x), \epsilon)$, then the noise would simply be ϵ . If the variance of ϵ is large, the noise would be large. Therefore, the same ideal regressor function $\bar{y}(x)$ would perform worse with a higher noise.

If we are comparing this to the throwing-darts analogy, we can imagine the ideal function $\bar{y}(x)$ to be the bull's eye that we must hit. The different algorithms \mathcal{A} represent different players throwing the darts. When one algorithm (player) is chosen, their vision can be skewed (perhaps their glasses is off), leading them to think that the target $\bar{h}(x)$ is somewhere else. If their target is far away from the bull's eye (i.e. $[\bar{h}(x) - \bar{y}(x)]^2$ is high), then their bias is high. Their skills in darts may just be bad, so even if their vision is good and they have a good sense of where to hit (low bias), for each time they throw the dart (i.e. each time the regressor function $h_{\mathcal{D}}$ is generated from data), it may be very off from their ideal target $\bar{h}(x)$.

Therefore, if you are a data scientist and you find that your regression function is not accurate enough, it is your job to find out whether your bias is too high, your variance is too high, or whether there is too much noise, and fix the proper component. Generally, we would try to minimize this cost function, visualized below.

Figure 3: Visualization of the bias-variance tradeoff showing how model complexity affects error components

3 Hierarchical Modeling

Given a training data set $\mathcal{D} = (\mathbf{X}, \mathbf{Y})$ comprised of N pairs of observations with corresponding target variables $\{(x_i, y_i)\}_{i=1}^N$ ($x_i \in \mathbb{R}^D, y_i \in \mathbb{R}$), the goal is to predict the value of y for a new value of x . We first construct a *statistical model* (more explained in next next subsection) by assuming that there exists some function $f(x)$ of some form such that the y_i 's have been generated by inputting the x_i 's into f , followed by a random residual term. We assume that the data \mathcal{D} has been sampled independently, but this may not always be a justifiable assumption in practice. Under this model, which we denote \mathcal{M}_i , we further assume that f can be parameterized by a vector θ , so therefore, we assume that

$$y = f(x, \theta) + \epsilon, \quad \epsilon \sim \text{Residual}(\beta) \quad (32)$$

where β is some collection of parameters that determine the error function.

- The frequentist perspective reduces this problem to finding the value of θ that maximizes the likelihood. That is, we must find

$$\theta^* = \arg \max_{\theta} p(\mathcal{D} | \theta) = \arg \max_{\theta} \prod_{i=1}^N p(y_i | x_i, \theta) \quad (33)$$

and claiming that $y = f(x, \theta^*)$ is the function of best fit. This is a quite straightforward (hopefully convex) optimization problem, which can be done in many ways (e.g. batch/sequential gradient descent, solving normal equations, etc.).

- The Bayesian approach attempts to construct a *distribution* of the values of θ . Clearly, this vector θ would be an element in some multidimensional Euclidean space, and we want to define a posterior density $p(\theta | \mathcal{D})$ across this space that tells us the probability of θ . Using Bayes rule,

$$p(\theta | \mathcal{D}) \propto p(\mathcal{D} | \theta) p(\theta) \quad (34)$$

we see that we must define some prior distribution $p(\theta)$ on θ . We can assume that this prior is defined with some distribution

$$\theta \sim \text{Dist}_{\theta}(\gamma) \quad (35)$$

where γ is a collection of parameters on θ . Knowing this prior of θ will allow us to get the posterior of $\theta | \mathcal{D}$. The not-so-complete Bayesian treatment would treat this γ as a known constant. But note that there is still uncertainty of whether θ comes from $\text{Dist}_{\theta}(\gamma)$ for one value of γ , compared to another value of γ . This uncertainty requires us to treat γ as now a **hyperparameter**, that is a parameter for the distribution of a parameter, and this distribution of γ , which we can denote

$$\gamma \sim \text{Dist}_{\gamma}(\xi) \quad (36)$$

is called a **hyperprior**. We can construct higher and higher level hyperpriors on top of this as much as we want, which will lead to more flexibility in our model (but more computationally expensive). This is known as **hierarchical priors**. Generally, we will only go up to the level of one hyperparameter.

Let us summarize how we would conduct the Bayesian method step by step. We first have to determine how many levels of hierarchical priors we are accounting for. Say that we will treat ξ as a constant, and consider the parameter θ along with its hyperparameter γ . Our goal is to compute the posterior $p(\theta | \mathcal{D})$.

1. Since there is uncertainty over the value of θ depending on γ , we can marginalize over γ to get

$$p(\theta | \mathcal{D}) = \int p(\theta | \mathcal{D}, \gamma) p(\gamma | \mathcal{D}) d\gamma \quad (37)$$

If the situation calls for it, we could also compute the posterior by doing Bayes rule first to get $p(\theta | \mathcal{D}) \propto p(\mathcal{D} | \theta) p(\theta)$, but then we would have to calculate both $p(\mathcal{D} | \theta)$ and $p(\theta)$ by marginalizing each over γ , which would lead to complications.

2. To calculate $p(\theta | \mathcal{D}, \gamma)$, note that the formula for the posterior density of θ given \mathcal{D} is $p(\theta | \mathcal{D}) \propto p(\mathcal{D} | \theta)p(\theta)$, where $p(\theta)$ is a density function of θ and parameter γ , which means that $p(\theta | \mathcal{D})$ would be a density function of θ and parameter γ . But since γ is fixed, the posterior

$$p(\theta | \mathcal{D}, \gamma) \propto p(\mathcal{D} | \theta, \gamma)p(\theta | \gamma) \quad (38)$$

is a density function of θ with fixed constant γ . This can be easily calculated because the prior $p(\theta | \gamma)$ is of distribution $\text{Dist}_\theta(\gamma)$ and the likelihood $p(\mathcal{D} | \theta, \gamma)$ is the product of densities of y given fixed θ .

3. To calculate $p(\gamma | \mathcal{D})$, we first use Bayes rule to get

$$p(\gamma | \mathcal{D}) \propto p(\mathcal{D} | \gamma)p(\gamma) \quad (39)$$

This can be easily calculated because the prior $p(\gamma)$ is of distribution $\text{Dist}_\gamma(\xi)$ of given ξ . The likelihood can be marginalized over θ to get

$$p(\mathcal{D} | \gamma) = \int p(\mathcal{D} | \theta, \gamma)p(\theta | \gamma) d\theta \quad (40)$$

where $p(\theta | \gamma)$ is a function of θ with given parameter γ , and $p(\mathcal{D} | \theta)$ is the product of the individual likelihoods.

But remember that this was all assumed under model \mathcal{M}_i , so the posterior density $p(\theta^i | \mathcal{D})$ of the θ^i parameterizing our best-fit function is really

$$p(\theta^i | \mathcal{D}, \mathcal{M}_i) \quad (41)$$

where we index the parameter of model \mathcal{M}_i to be θ^i , with a superscript (since we may mistake subscript indices to be the components of θ).
